Abstract. Hub-and-spoke systems are widely used in freight transportation. In freight transportation, hub operations such as scanning, unloading sorting, weighting, and loading of consignments takes significant time. Motivated by the significance of service level at the hubs in hub-and-spoke systems, this paper presents a model for designing a capacitated single allocation $\rho$-hub location with stochastic demand and time-based service level constraints at the hubs. The proposed model seeks to simultaneously determine the location and the capacity of hubs and allocate flows to hubs so as to minimize the fixed cost of locating hubs and equipping them with processing capacity and the variable transportation costs subject to the service level constraints. The problem is setup as a network of spatially distributed hubs modelled as priority queues with Poisson arrival rate and exponential service times. We present a matrix geometric approach to deal with the service level constraints associated with priority flow classes. The numerical experiments are conducted with Civil Aeronautics Board (CAB) data sets. Through a numerical example, we illustrate the impact of service-level constraints on the configuration of the network. We show that substantial improvement in service level can be achieved with small increase in total costs in the design of hub-and-spoke systems.

Keywords: Hub location, capacity selection, network design, service-level constraints, priority queues, matrix geometric method.

1. Introduction

Freight transportation has emerged as one of the most critical parts of the global economy with the rising volume of trade across the globe. Freight transportation through hub-and-spoke network involves operations at hubs such as scanning, unloading sorting, weighting, and loading of consignments. For example, companies such as FedEx, UPS, DHL, and the United States Postal Service (USPS) receive and deliver millions of packages every day. UPS handles 2.3 million packages a day, accounting for 22% of its domestic revenues. Every night, at the FedEx Memphis hub, 2.2 million packages are scanned, sorted, weighted, and routed. These packages are not homogenous and have different service delivery requirements. With such large volumes of packages transported between many different origin-destination points, many sorting hub centers are involved. While some of the packages are for regular delivery that takes a week or more (low priority consignment), others are time-sensitive and have to be expedited (high priority consignments) for delivery within 24 hours. The configuration of the hub-and-spoke network plays an important role in the distribution of such large volumes of packages transported between many different origin-destination points. It is paramount that the delivery networks are designed and operated efficiently so as to be able to meet the time-based service delivery guarantees. For example, FedEx has strategically designed its hub-and-spoke network and located its hub at Memphis, Tennessee in order to serve the entire United States by providing overnight service to the entire nation and serving 95% of the global economy (220 countries on six continents) customers within 24-48 hours.

Hub-and-spoke network design problems have been widely studied. The first mathematical formulation of discrete hub location problems was proposed by O’Kelly (1987). Since then several variants and extensions have been formulated and studied. Amongst the hub location problems, the one that has received the most attention in literature is the $p$-hub median problem (Alumur and Kara, 2008). In the classical $p$-hub median problem, the objective is to locate $p$ hubs from a set of $n$ nodes in a graph, establishing a complete subgraph of these hubs by allocating spoke to the hubs and directing flows between pairs of origins-destinations through the hubs in the network. Single allocation $p$-hub median problem, implies that all the incoming and outgoing traffic of every demand node is routed through a single hub; whereas in multiple allocation, each demand node can receive and send flows through more than one hub. The single allocation $p$-hub median problem and its variants have been studied by O’Kelly (1987), Campbell (1994b), O’Kelly et al. (1995), Campbell (1996), Ernst and Krishnamoorthy (1996), Skorin-Kapov et al. (1996), Smith et al. (1996), Song and Park (2000), Abdinnour-Helm (2001), Ebery (2001), Yaman (2009), and Elhedhli and Wu (2010) among others. Solution methods for hub location problems include GRASP (greedy randomized adaptive search procedure) (Klincewicz, 1992), tabu search (Klincewicz, 1992), simulated annealing (Ernst and Krishnamoorthy, 1996), genetic algorithm (Topcuoglu et al., 2005; Kratica et al., 2007), evolutionary algorithms (Koksalan and Soylu, 2010), Neural networks (Smith et al., 1996), Lagrangean relaxation (Elhedhli and Hu, 2005; Contreras et al., 2009; Elhedhli and Wu, 2010), Benders decomposition (Camargo et al., 2008, 2009; Contreras et al., 2012), branch and bound (Ernst and Krishnamoorthy, 1996; Ebery, 2001),
among others. For more details, interested readers are referred to surveys by Campbell et al. (2002), Alumur and Kara (2008) and Campbell and O’Kelly (2012).

Marianov and Serra (2003) present models for location of hubs in airline networks, where hubs are modelled as M/D/c queues. Their model considers probabilistic service level constraints, which limit the number of planes in the queue. The model is solved using a tabu search based heuristic approach. Sim et al. (2009) present the stochastic p-hub center problem and use a chance-constrained formulation to model the minimum service-level requirement. The model takes into account the variability in travel times when designing the hub network so that the maximum travel time through the network is minimized. They present a linear MIP formulation for the problem, under the assumption that travel times on the arcs are independent normal random variables. Yang (2009) presents a two-stage stochastic programming model for hub location and route planning in air freight transportation under seasonal demand variations. Contreras et al. (2011) study hub location problems in which uncertainty is associated with demand and transportation costs. They show that stochastic models with uncertain demand or dependent transportation costs are equivalent to their associated deterministic expected value problem (EVP), in which random variables are replaced by their expected values. However, in case of uncertain independent transportation costs, the corresponding stochastic model is not equivalent to its EVP, for which they present a solution methodology based on Monte-Carlo simulation that integrates a sample average approximation scheme with a Benders decomposition algorithm.

The objective of this paper is to study the effect of incorporating service level constraint for the different classes of flows (customers) on the configuration of the hub-and-spoke network and to analyze the tradeoffs between hub location and capacity acquisition cost and transportation cost. We present a model that simultaneously determines the location and the capacity of hubs and allocate flow to these hubs such that the service-level constraints for the different customer classes are met. The service level constraint is defined at the fraction of flow served at a hub within a sojourn time (waiting in queue + service time) and hence is based on the complete distribution of sojourn time, and not just their averages. The problem is setup as a network of spatially distributed hubs modelled as priority queues with Poission arrival rate and exponential service times. We present a matrix geometric approach to deal with the service level constraints associated with priority flow classes. To the best of our knowledge, this is the first paper to model hubs as priority queues to account for non-homogenous consignment classes that have different delivery time requirements.

The remainder of the paper is organized as follows. In §2, we present the description of the problem and the mathematical formulation. In section 3, we present the solution methodology. §4 presents the sensitivity analysis and managerial insights using an illustrative example. Finally, we conclude with future research directions in §5.
2. Problem Description and Model Formulation

We extend the formulation of the basic uncapacitated single-allocation $p$-hub median problem (USA$^p$HMP) proposed by Skorin-Kapov et al. (1996) to build our model. For that, consider a graph $G = (N, A)$, where $N$ be the set of nodes that exchange traffic and are potential hub locations. Let $k$ and $m$ be indices for potential hub locations and $i$ and $j$ be indices for the origin and destination nodes. If $\lambda_{ij}$ is the amount of flow to be shipped from origin node $i$ to destination $j$, then the total transportation cost of routing the flow from origin $i$ to destination $j$ routed via hubs $k$ and $m$ is given by: $C_{ijkm} = \lambda_{ij}(\chi c_{ik} + \beta c_{km} + \delta c_{mj})$, where $\chi$ is coefficient of the collection cost (per unit flow) from any origin to any hub node, $\delta$ is the coefficient of the collection cost (per unit flow) from any hub node to any destination, $\beta$ is the discount factor from any hub node to any other hub node, and $c_{ij}$ is the transportation cost per unit of flow from node $i$ to node $j$. Let $z_{ik}$ be 1 if node $i$ is allocated to hub $k$ and 0 otherwise; in particular, $z_{kk} = 1$ implies that node $k$ is selected as a hub. The routing variable $x_{ijkm}$ equals 1 if the total flow from node $i$ to node $j$ is routed via hubs located at $k$ and $m$, in that order. With these notations, the formulation of (USA$^p$HMP) is as follows:

$$\text{[USA}^p\text{HMP]} : \min \sum_i \sum_j \sum_k \sum_m C_{ijkm} x_{ijkm}$$  \hspace{1cm} (1)

s.t. \begin{align*}
\sum_k z_{ik} &= 1 & \forall i \hspace{1cm} (2) \\
z_{ik} &\leq z_{kk} & \forall i, k \hspace{1cm} (3) \\
\sum_k z_{kk} &= p & \forall k \hspace{1cm} (4) \\
\sum_k x_{ijkm} &= z_{ik} & \forall i, j, k \hspace{1cm} (5) \\
\sum_k x_{ijkm} &= z_{jm} & \forall i, j, m \hspace{1cm} (6) \\
x_{ijkm}, z_{ik} &\in \{0, 1\} & \forall i, j, k, m \hspace{1cm} (7)
\end{align*}

The objective function (1) minimizes the sum of total transportation cost of flow of commodities between all the origin-destination node pairs. Constraint set (2) ensures that every node is assigned to exactly one hub. Constraint set (3) guarantees that a node will be assigned to a open hub. Constraint (4) ensures that exactly $p$ hubs are opened in the network. Constraint sets (5) and (6) ensure that all the traffic between an origin-destination pair have been routed via a hub sub-network.

We extend the model to account for stochastic demand and service level constraints for the priority consignment classes. Without the loss of generality, the model remains valid for multiple consignment classes, $N \geq 2$. Let $h$ represent the high priority class customers and $l$ represent the lower priority class customers. We assume that the arrival rate of flow (demand) from high and low priority class customers that has to be shipped from origin $i$ to destination $j$ is an independent random variable that follows a Poisson process with mean $\lambda_{ij}^h$ and $\lambda_{ij}^l$ respectively. In that case, the aggregate flow rate through hub $k$ is also a random
variable that follows a Poisson process with mean \( \Lambda_k = \sum_i \sum_j (\lambda_{ij}^h + \lambda_{ij}^l) z_{ik} \) (due to the superposition of Poisson processes). Let us model service times at hubs as random variables that follow an exponential distribution with mean \( \mu_{kl} \), where \( l \) is the index for capacity level. The service rate reflects the server capacity or essentially the units of flow a hub can serve in a given time period. For every hub node \( k \), we allow the model to select one of the discrete capacity levels, \( \mu_{k1}, \mu_{k2}, ..., \mu_{kN} \) with fixed costs \( F_{k1}, F_{k2}, ..., F_{kN} \) respectively. The fixed cost refers to the cost of using the hub (airport) amortized over the planning period. Each hub can be modelled as an M/M/1 queue, where the mean service rate of hub \( k \), if it is allocated capacity level \( l \), is given by \( \mu_k = \sum_{i=1}^{l} \mu_{kn} y_{kn} \). In steady-state, the stability condition of the queueing system implies that at every hub node, the arrival rate of any consignment is less than the total service rate: \( \Lambda_k < \mu_k \), \( \forall k \). Alternatively, if \( \rho_k \) is the utilization of hub \( k \) \( (\rho_k = \Lambda_k / \mu_k \) then \( \rho < 1 \).

We specify the service level constraints as the fraction of flow served within a specified sojourn time (waiting in queue + service time). This can expressed as the probability that a flow spends more than \( \tau \) time units in service at hubs does not exceed \( \alpha \) for some finite \( \tau \) and \( \alpha \in (0, 1) \). For a given flow routing \( x \) and location and capacity level \( y \), let the arrival rates and service rate at a hub \( k \) be denoted by \( \Lambda^h_k(x), \Lambda^l_k(x) \) and \( \mu_k(y) \). If we let \( W^h_k(A_k, \mu_k) \) and \( W^l_k(A_k, \mu_k) \) denote the total time spent by the two classes in the system at hub \( k \) and \( \tau^h \) and \( \tau^l \) are their target service times, then the service level can be expressed as follows:

\[
P\{W^h_k(A_k(x), \mu_k(y)) \leq \tau^h \} \geq \alpha h z_{kk} \quad \forall k
\]

\[
P\{W^l_k(A_k(x), \mu_k(y)) \leq \tau^l \} \geq \alpha l z_{kk} \quad \forall k
\]

The resulting integer programming model is as follows:

\[
[P] : \quad \text{min} \quad \sum_i \sum_j \sum_k \sum_m C_{ijkm} x_{ijkm} + \sum_k \sum_{l \in L_k} F_{kl} y_{kl}
\]

s.t. \( (2) - (6) \)

\[
\sum_i \sum_j (\lambda_{ij}^h + \lambda_{ij}^l) z_{ik} \leq \sum_{l \in L_k} \mu_{kl} y_{kl} \quad \forall k
\]

\[
\sum_{l \in L_k} y_{kl} = z_{kk} \quad \forall k
\]

\[
P\{W^h_k(A_k(x), \mu_k(y)) \leq \tau^h \} \geq \alpha h z_{kk} \quad \forall k
\]

\[
P\{W^l_k(A_k(x), \mu_k(y)) \leq \tau^l \} \geq \alpha l z_{kk} \quad \forall k
\]

\[
x_{ijkm}, y_{kl}, z_{ik} \in \{0, 1\} \quad \forall i, j, k, m, l \in L_k, n
\]

The underlying model is difficult to solve due to the lack of closed form expression for service-level constraint (12) for lower priority class.
3. Solution Methodology

3.1. Estimation of Service-Level Function of High Priority Class Customers

The tail of the sojourn time distribution \( S_h^k(\cdot) \) for high priority customers in a preemptive priority queue is known to be exponential and is given by:

\[
S_h^k(\cdot) = P(W_h^k \leq \tau^h) = 1 - e^{-(\mu_k - \Lambda_h^k)W}
\]

The service level constraint for the high priority customer (12) can be expressed as a linear constraint as follows:

\[
\sum_{l \in L_k} \mu_{kl}y_{kl} - \sum_{i} \sum_{j} \lambda_{ij}^h z_{ik}^h \geq -\ln(1 - \alpha_h)n_k
\quad \forall k
\]

**Proposition 1:** The sojourn time distribution of higher priority customers \( S_h^k(x, y, z, \tau^h, \alpha_n) \) is (i) concave in \( \mu_k \) and (ii) concave in \( \Lambda_h^k \).

Differentiating \( S_h^k(\cdot) \) w.r.t. \( \mu_k \) twice, we get \( \frac{\delta^2 S_h^k(\cdot)}{\delta \mu_k^2} < 0 \), which proves that the function is concave in \( \mu_k \). Similarly, differentiating \( S_h^k(\cdot) \) w.r.t. \( \Lambda_h^k \) twice, we get \( \frac{\delta^2 S_h^k(\cdot)}{\delta \Lambda_h^k^2} < 0 \), which proves that the function is concave in \( \Lambda_h^k \).

3.2. Estimation of Service-Level Function of Low Priority Class Customers

In this subsection, we describe a procedure based on matrix geometric methods for estimating the service level function of low priority class customers \( S_l^k(\cdot) \) and its subgradients. Details regarding this method can be found in Neuts (1981) and Latouche and Ramaswami (1999). The matrix-geometric methods can provide near-exact estimates of service level function in some cases.

3.2.1. Joint Stationary Queue Length Distribution

Let us determine the joint distribution of queue lengths. For that, let the number of high and low priority customers in the system (including the one in the service) at time \( t \) be denoted by \( N_h(t) \) and \( N_l(t) \), respectively. We assume that \( N_l(t) \geq 0 \) (infinite low priority class buffer size) whereas \( 0 \leq n_h \leq M \) (the buffer size of the high priority customers in the system be \( M \)). No other state variables are required to model the system since the service is exponential and it is not necessary to keep track of which type of customer the server is attending to. As long as there is at least one high priority customer present in the system, the system must be busy attending to high priority queue. Therefore, \( N_h(t) \) and \( N_l(t) \) are the state variables representing the number of high and low priority customers in the system at time \( t \), and \( \{N(t)\} := \{N_l(t), N_h(t), t \geq 0\} \) is a continuous-time two-dimensional Markov chain with state space \( \{n = (n_l, n_h)|n_l \geq 0, \ 0 \leq n_h \leq M\} \). The key idea we employ here is that \( \{N(t)\} \) is a quasi-birth-and-death (QBD) process, which allows us to develop a matrix geometric solution for the joint distribution of the number of customers of each class in the...
system.

In the Markov process \( \{N(t)\} \), a transition can occur only if a customer of either class arrives or a customer of either class is served. For example, with the arrival of a high priority customer with rate \( \lambda_h \), the system transits from state \( n = \{(n_t, n_h)\} \) to \( n' = \{(n_t, n_h+1)\} \) and with the arrival of a low priority customer with rate \( \lambda_l \), the system transits from state \( n \) to \( n'' = \{(n_t+1, n_h)\} \). Similarly, with the service of a high priority customer with rate \( \mu \), the system transits from state \( n = \{(n_t, n_h)|n_t \geq 0, n_h > 0\} \) to \( \tilde{n} = \{(n_t, n_h-1)\} \) and with the service of a low priority customer with rate \( \mu \), the system transits from state \( n = \{(n_t, n_h)|n_t \geq 0, n_h = 0\} \) to \( \tilde{n} = \{(n_t-1, n_h)\} \). We order the states of the system lexicographically, i.e. \( (0,0), (0,1), (0,2), \ldots, (0,M); (1,0), (1,1), (1,2), \ldots, (1,M); \ldots; (i,0), (i,1), (i,2), \ldots, (i,M) \), and define \( \pi_{(i,s)} \) to be the stationary probability of the state \( (i,s) \). With \( n_t \) serving as the level and \( n_h \) as the sub-level, the infinitesimal generator of the chain \( \{N(t)\} \) for \( n_t = 0,1,2 \) and \( n_h = 0,1,\ldots,M \) is given by:

\[
Q = \begin{pmatrix}
(0,0) & (0,1) & (0,\ldots) & (0,M) & (1,0) & (1,1) & (1,\ldots) & (1,M) & (2,0) & (2,1) & (2,\ldots) & (2,M) \\
(0,0) & -\delta_1 & \lambda_h & \mu & -\delta_2 & \lambda_h & \mu & -\delta_2 & \lambda_h & \mu & -\delta_3 & \lambda_l \\
(0,1) & \mu & -\delta_2 & \lambda_h & \mu & -\delta_2 & \lambda_h & \mu & -\delta_2 & \lambda_h & \mu & -\delta_3 & \lambda_l \\
(0,2) & \mu & -\delta_2 & \lambda_h & \mu & -\delta_2 & \lambda_h & \mu & -\delta_2 & \lambda_h & \mu & -\delta_3 & \lambda_l \\
(2,0) & \mu & -\delta_2 & \lambda_h & \mu & -\delta_2 & \lambda_h & \mu & -\delta_2 & \lambda_h & \mu & -\delta_3 & \lambda_l \\
(2,1) & \mu & -\delta_2 & \lambda_h & \mu & -\delta_2 & \lambda_h & \mu & -\delta_2 & \lambda_h & \mu & -\delta_3 & \lambda_l \\
(2,\ldots) & \mu & -\delta_2 & \lambda_h & \mu & -\delta_2 & \lambda_h & \mu & -\delta_2 & \lambda_h & \mu & -\delta_3 & \lambda_l \\
(2,M) & \mu & -\delta_2 & \lambda_h & \mu & -\delta_2 & \lambda_h & \mu & -\delta_2 & \lambda_h & \mu & -\delta_3 & \lambda_l \\
\end{pmatrix}
\]

where \( \delta_1 = \lambda_h + \lambda_l, \delta_2 = \lambda_h + \lambda_l + \mu, \) and \( \delta_3 = \mu + \lambda_l. \)

The entries of the infinitesimal generator matrix can be grouped into blocks to form a block-tridiagonal matrix as follows:

\[
Q = \begin{pmatrix}
B_0 & A_0 & & & \\
A_2 & A_1 & A_0 & & \\
A_2 & A_1 & A_0 & & \\
& & \ddots & \ddots & \ddots \\
& & \ddots & \ddots & \ddots \\
\end{pmatrix}
\]

where \( B_0, A_0, A_1, A_2 \) are square matrices of order \( M + 1 \). These matrices can be easily constructed using the transition rates described above.
\[
A_0 = \begin{pmatrix}
\lambda_l &  &  & \\
 & \lambda_l & \cdots & \\
 & & \ddots & \\
 & & & \lambda_l
\end{pmatrix};
\quad A_2 = \begin{pmatrix}
\mu &  &  &  &  & \\
 & 0 &  &  &  & \\
 & & 0 &  &  & \\
 & & & \ddots &  & \\
 & & & & 0 & \\
 & & & & & 0
\end{pmatrix};
\quad B_0 = \begin{pmatrix}
* & \lambda_h &  &  & \\
\mu & * & \lambda_h &  & \\
& \mu & * & \lambda_h & \\
& & \ddots & \ddots & \\
& & & \ddots & *
\end{pmatrix}
\]

where * is such that \(A_0 \mathbf{e} + B_0 \mathbf{e} = \mathbf{0}\). \(A_1 = B_0 - A_2\).

The matrix \(B_0\) contains all transitions when no low priority customers are present in the system and the server is devote to serving high priority customers. \(A_1\) contains all transitions that represents arrivals of low priority customers, whereas \(A_{-1}\) contains transitions corresponding to the service of low priority customer. Since \(n_l\) can only change by \(\pm 1\), the only non-zero matrices are \(A_1, A_0\), and \(A_{-1}\).

We denote the steady-state probability vector of \(\{N(t)\}\) by \(\pi \equiv (\pi_0, \pi_1, \pi_2, \pi_3, \ldots)\), where \(\Xi_i \equiv (\pi_{(i,0)}, \pi_{(i,1)}, \pi_{(i,2)}, \pi_{(i,3)}, \ldots, \pi_{(i,M)})\). The vector \(x\) can be partitioned by levels into sub vectors \(x_i, i \geq 0\), where \(x_i = [x_{i0}, x_{i1}, \ldots, x_{iM}]\) is the stationary probability of states in level \(i\) \((n_l = i)\). Thus, \(x = [x_0, x_1, x_2, x_3, \ldots, \ldots]\). \(x\) can be obtained using a set of balance equations, given in matrix form by the following standard relations (Latouche and Ramaswami, 1999; Neuts, 1981):

\[
\pi Q = \mathbf{0}; \quad \pi_{i+1} = \pi_i R
\]

where \(R\) is the minimal non-negative solution to the matrix quadratic equation:

\[
A_0 + RA_1 + R^2A_2 = \mathbf{0}
\]

The matrix \(R\) can be computed using well known methods (Latouche and Ramaswami, 1999). A simple iterative procedure often used is:

\[
R(0) = 0; \quad R(n + 1) = - [A_0 + R^2(n)A_2] A_1^{-1}
\]

The probabilities \(\pi_0\) are determined from:

\[
\pi_0(B_0 + RA_2) = \mathbf{0}
\]

subject to the normalization equation:

\[
\sum_{i=0}^{\infty} \pi_i \mathbf{e} = \pi_0 (I - R)^{-1} \mathbf{e} = 1
\]
where $\mathbf{e}$ is a column vector of ones of size $M + 1$.

These steady state probabilities will be used in estimating the service-level for low priority customers.

Note that this matrix geometric procedure is very efficient for obtaining the near-exact performance measures through judicious choice of the number of states. The computational implementation of the matrix geometric method, however, requires the number of states in the QBD process to be finite. For this, we treat the queue length of high priority customers (including the one in service) to be of finite size $M$, but of size large enough for the desired accuracy of our results. Since high priority customers are always served in priority over low priority customers, it is reasonable to assume that its queue size will always be bounded by some large number. However, the computational effort grows rapidly with the number of states and customer classes.

3.2.2. Estimation of Service-Level for Low Priority Class $S_l(\cdot)$

We derive the distribution of sojourn time of low priority customers. The sojourn time of a low priority customer $W^f_j$ is the time between its arrival to the hub till it completes its service (i.e. waiting time in queue plus the time in service). It may be preempted by one or more of the high priority customers for service. Hence it is difficult to characterize the distribution of the service-level $S^l_k(\cdot)$. However, Ramaswami and Lucantoni (1985) present an efficient algorithm for the derivation of complementary distribution of stationary waiting times in phase-type and QBD processes. Leeman (2001) uses the same approach to derive the complementary distribution of stationary waiting times in more complex queuing system. We adopt their approach to derive the distribution of sojourn time of low priority customers.

Let us consider a tagged low priority customer entering the system. The time spent by the tagged customer depends on the number of customers of either class already present in the system ahead of it, and also on the number of subsequent high priority arrivals before it completes its service. All subsequent low priority arrivals, however, have no influence on its time spent in the system. The tagged customer’s time in the system is, therefore, simply the time until absorption in a modified Markov process $\tilde{\mathbf{N}}(t)$, obtained by setting $\lambda_l = 0$. Consequently, matrix $\tilde{\mathbf{A}}_0$, representing transitions to a higher level, becomes a zero matrix.

We define an absorbing state, call it state $0'$, as the state in which the tagged customer has finished its service. The infinitesimal generator for this process can be represented as:

$$
\tilde{\mathbf{Q}} = \begin{pmatrix}
0 & 0 & 0 & 0 & 0 & \cdots \\
\begin{array}{c}
B_0 \\
A_2 \\
A_1 \\
A_2 \\
\vdots
\end{array} & 0 & \begin{array}{c}
0 \\
A_1 \\
0 \\
\cdots \\
\cdots
\end{array} & \begin{array}{c}
0 \\
0 \\
A_1 \\
\cdots \\
\cdots
\end{array} & \begin{array}{c}
0 \\
0 \\
A_1 \\
\cdots \\
\cdots
\end{array}
\end{pmatrix}
$$

where, $\tilde{B}_0 = B_0 + A_0$; $\tilde{A}_1 = A_1 + A_0$; and $b_0 = [\mu \ 0 \ \cdots \ 0]^T_{M+1}$. The first row and column in $\tilde{Q}$ corresponds to the absorbing state $0$. The time spent in system by the tagged customer, which is the time until absorption in the modified Markov process with rate matrix
\( \hat{Q} \), depends on the arrival rates \( \lambda_h \) and \( \lambda_l \) and the service rate \( \mu \). For given arrival rates \((\lambda_h, \lambda_l)\) and service rate \( \mu \), the distribution of the time spent by a low priority customer in the system is \( S_l^f(\tau) = 1 - S_l^f(\tau) \), where \( S_l^f(\tau) \) is the stationary probability that a low priority customer spends more than \( y \) units of time in the system. Further, let \( S_l^f(y) \) denote the conditional probability that a tagged customer, who finds \( i \) low priority customers ahead of it, spends a time exceeding \( y \) in the system. The probability that a tagged customer finds \( i \) low priority customers is given, using the PASTA property, by \( X_i = x_0 R^i \). \( S_l^f(y) \) can be expressed as:

\[
S_l^f(y) = \sum_{i=0}^{\infty} x_i S_k^l(y) e^{15}
\]

where \( S_k^l(y) \) is the stationary probability that a low priority customer spends more than \( i \) units of time in the system. Therefore, for its time in the system to exceed \( y \), at most \( i \) of the \( n \) Poisson points may correspond to transitions to lower levels (i.e., service completions of low priority customers). Therefore,

\[
S_k^l(y) = \sum_{i=0}^{\infty} d_n e^{-\gamma y} \left( \sum_{v=0}^{i} G_v^{(n)} e \right), \quad i \geq 0 \tag{16}
\]

where, \( G_v^{(n)} \) is a matrix such that its entries are the conditional probabilities, given that the system has made \( n \) transitions in the discrete-time Markov process with rate matrix \( \hat{Q} \), that \( v \) of those transitions correspond to lower levels (i.e., service completions of low priority customers). Substituting the expression for \( S_k^l(y) \) from (16) into (15), we obtain:

\[
S_l^f(y) = \sum_{n=0}^{\infty} d_n e^{-\gamma y} \left( \sum_{v=0}^{i} G_v^{(n)} e \right), \quad n \geq 0 \tag{17}
\]

where, \( d_n \) is given by: \( d_n = \sum_{i=0}^{\infty} x_i R^i \sum_{v=0}^{i} G_v^{(n)} e, \quad n \geq 0. \)
Now,

\[ \sum_{i=0}^{\infty} R_i \sum_{v=0}^{n+1} G_{v}^{(n)} e = \sum_{i=0}^{n+1} R_i \sum_{v=0}^{n} G_{v}^{(n)} e + \sum_{v=0}^{n} R_i \sum_{i=n+2}^{\infty} G_{v}^{(n)} e \]

(since \( G_{v}^{(n)} = 0 \) for \( v > n \))

\[ = \sum_{v=0}^{n+1} R_i G_{v}^{(n)} e + (I-R)^{-1} R^{n+2} e \]

(since \( \sum_{v=0}^{n} G_{v}^{(n)} e = e \))

\[ = \sum_{v=0}^{n} (I-R)^{-1} (R^{v} - R^{n+2}) G_{v}^{(n)} e + (I-R)^{-1} R^{n+2} e \]

\[ = \sum_{v=0}^{n} (I-R)^{-1} R^{v} G_{v}^{(n)} e + (I-R)^{-1} R^{n+1} G_{n+1}^{(n)} e \]

(since \( \sum_{v=0}^{n+1} G_{v}^{(n)} e = e \))

\[ = \sum_{v=0}^{n} (I-R)^{-1} R^{v} G_{v}^{(n)} e \]

\[ = (I-R)^{-1} H_n e \]

\[ n \geq 0 \]

where, \( H_n = \sum_{v=0}^{n} R^{v} G_{v}^{(n)} \).

Therefore,

\[ S_k^{l}(L_i) = 1 - S_k^{l}(L_i) = \sum_{n=0}^{\infty} e^{-\gamma L_i} (\gamma L_i)^n \frac{n!}{n!} x_0 (I-R)^{-1} H_n e \]

(18)

\( H_n \) can be computed recursively as:

\[ H_{n+1} = H_n \hat{A}_1 + RH_n \hat{A}_2; \quad H_0 = I \]

Therefore, for given prices \( (p^k, p^k) \) and service rate \( (\mu^k) \), \( S_k^{l}(. \) in (16) can be computed using (18).

**Proposition 2:** The sojourn time distribution of lower priority customers \( S_k^{l}(x, y, z, \tau^n, \alpha_n) \) is (i) concave in \( \mu^k \) and (ii) concave in \( \Lambda_k^l \).

The plots of \( S_k^{l}(. \) vs. \( \mu^k \) and \( S_k^{l}(. \) vs. \( \Lambda_k^l \) obtained using the matrix geometric method show that the components of \( S_k^{l}(. \) are concave. Intuitively, one would expect that the sojourn time increases with decreasing marginal returns as the service rate increases. Furthermore, it should decrease with increasing marginal returns as the arrival rate increases.

3.3. Linearization of Service-Level Constraints

Under this concavity assumption, the service level for low priority customers \( S_k^{l}(.) \) can be approximated by a set of supporting hyperplanes that are tangent to \( S_k^{l}(.) \) at various points.
Hub-and-Spoke System Design for Freight Transportation with Priority Consignment Classes

\[ S^l_k(.) = \min_{q \in Q} \left\{ S^l_{kq}(. \mid \Lambda - \Lambda^l_k \partial S^l_{kq}(. \mid \Lambda^h_k) + (\Lambda^h_k - \Lambda^h_k) \partial S^h_{kq}(. \mid \Lambda^h_k) + (\mu_k - \mu^q_k) \partial S^q_{kq}(. \mid \mu_k) \right\} \forall k \quad (19) \]

where \( S^l_{kq}(. \mid \Lambda - \Lambda^l_k \partial S^l_{kq}(. \mid \Lambda^h_k) + (\Lambda^h_k - \Lambda^h_k) \partial S^h_{kq}(. \mid \Lambda^h_k) + (\mu_k - \mu^q_k) \partial S^q_{kq}(. \mid \mu_k) \) denotes the value of function \( S^l_{kq}(. \mid \Lambda - \Lambda^l_k \partial S^l_{kq}(. \mid \Lambda^h_k) + (\Lambda^h_k - \Lambda^h_k) \partial S^h_{kq}(. \mid \Lambda^h_k) + (\mu_k - \mu^q_k) \partial S^q_{kq}(. \mid \mu_k) \) at a fixed point \((\Lambda^h_k, \Lambda^l_k, \mu_k)\), \(q \in Q\), and \(\partial S^h_{kq}(. \mid \Lambda^h_k)\) and \(\partial S^q_{kq}(. \mid \mu_k)\) are the subgradients of \( S^l_{kq}(. \mid \Lambda - \Lambda^l_k \partial S^l_{kq}(. \mid \Lambda^h_k) + (\Lambda^h_k - \Lambda^h_k) \partial S^h_{kq}(. \mid \Lambda^h_k) + (\mu_k - \mu^q_k) \partial S^q_{kq}(. \mid \mu_k) \) at points \((\Lambda^h_k, \Lambda^l_k, \mu_k)\).

This expression can be written as

\[ S^l_{kq}(. \mid \Lambda - \Lambda^l_k \partial S^l_{kq}(. \mid \Lambda^h_k) + (\Lambda^h_k - \Lambda^h_k) \partial S^h_{kq}(. \mid \Lambda^h_k) + (\mu_k - \mu^q_k) \partial S^q_{kq}(. \mid \mu_k) \leq \forall k, q \in Q \]

This implies that the service level constraint for low priority customers can be expressed as a set of linear constraints as follows:

\[
\frac{\partial S^l_{kq}(. \mid \Lambda - \Lambda^l_k \partial S^l_{kq}(. \mid \Lambda^h_k) + (\Lambda^h_k - \Lambda^h_k) \partial S^h_{kq}(. \mid \Lambda^h_k) + (\mu_k - \mu^q_k) \partial S^q_{kq}(. \mid \mu_k)}{\partial \mu_k} \leq \sum_{i \in L_k} \mu_{ik} y_{kl} + \sum_{i \in L_k} \sum_{j} \lambda_{ijk} z_{ik} \geq \left\{ \alpha^l - S^l_{kq}(. \mid \Lambda - \Lambda^l_k \partial S^l_{kq}(. \mid \Lambda^h_k) + (\Lambda^h_k - \Lambda^h_k) \partial S^h_{kq}(. \mid \Lambda^h_k) + (\mu_k - \mu^q_k) \partial S^q_{kq}(. \mid \mu_k) \right\} \forall k, q \in Q \quad (20) \]

The resulting linear MIP model \([PL]\) is as follows:

\[
\min \sum_{i} \sum_{j} \sum_{k} \sum_{m} C_{ijkm} x_{ijkm} + \sum_{k} \sum_{l \in L_k} F_{kl} y_{kl} \quad \text{s.t.} \quad (2) - (6) \quad (21)
\]

\[
\sum_{l \in L_k} y_{kl} = z_{kk} \quad \forall k \quad (22)
\]

\[
\sum_{l \in L_k} \mu_{ik} y_{kl} - \sum_{i \in L_k} \sum_{j} \lambda_{ijk} z_{ik} \geq -\ln(1 - a^h) \forall k, q \in Q \quad (23)
\]

\[
\frac{\partial S^l_{kq}(. \mid \Lambda - \Lambda^l_k \partial S^l_{kq}(. \mid \Lambda^h_k) + (\Lambda^h_k - \Lambda^h_k) \partial S^h_{kq}(. \mid \Lambda^h_k) + (\mu_k - \mu^q_k) \partial S^q_{kq}(. \mid \mu_k)}{\partial \mu_k} \leq \sum_{i \in L_k} \mu_{ik} y_{kl} + \sum_{i \in L_k} \sum_{j} \lambda_{ijk} z_{ik} \geq \left\{ \alpha^l - S^l_{kq}(. \mid \Lambda - \Lambda^l_k \partial S^l_{kq}(. \mid \Lambda^h_k) + (\Lambda^h_k - \Lambda^h_k) \partial S^h_{kq}(. \mid \Lambda^h_k) + (\mu_k - \mu^q_k) \partial S^q_{kq}(. \mid \mu_k) \right\} \forall k, q \in Q \quad (24)
\]

In the next subsection, we describe the procedure for estimating the subgradients of service level function \( S^l_{kq}(. \mid \Lambda - \Lambda^l_k \partial S^l_{kq}(. \mid \Lambda^h_k) + (\Lambda^h_k - \Lambda^h_k) \partial S^h_{kq}(. \mid \Lambda^h_k) + (\mu_k - \mu^q_k) \partial S^q_{kq}(. \mid \mu_k) \).

3.4. Estimation of Subgradients of the Service Level Function

We use finite difference method as it has been shown to provide better estimates of gradients (Andradottir, 1998; Atlason et al., 2004, 2008). Gradient estimation through finite difference method can be obtained using forward differences, backward differences, or central
In order to estimate the subgradients of a function (i.e., partial derivatives with respect to a continuous variable) using central finite differences, the function is evaluated at two different points. Then an estimate of the partial derivative at a particular value can be obtained as follows: In our case, the arrival rates $\Lambda^h_k$ and $\Lambda^l_k$ are continuous variables as $0 \leq x_{ij} \leq 1$, and service rate $\mu_k$ is a discrete variable as $y_{jk} \in \{0, 1\}$.

If $\frac{\partial S_j^l(\Lambda^h_k, \Lambda^l_k, \mu_j)}{\partial \Lambda^h_k}$, $\frac{\partial S_j^l(\Lambda^h_k, \Lambda^l_k, \mu_j)}{\partial \Lambda^l_k}$, and $\frac{\partial S_j^l(\Lambda^h_k, \Lambda^l_k, \mu_j)}{\partial \mu}$ denote the subgradient of $S_j^l(\Lambda^h_k, \Lambda^l_k, \mu_j)$, then the central finite difference estimate is obtained as follows:

$$
\frac{\partial S_j^l(\Lambda^h_k, \Lambda^l_k, \mu_k)}{\partial \Lambda^h_k} \approx \frac{\tilde{S}^l_k(\Lambda^h_k + d\Lambda^h_k, \Lambda^l_k, \mu_k) - \tilde{S}^l_k(\Lambda^h_k - d\Lambda^h_k, \Lambda^l_k, \mu_k)}{2d\Lambda^h_k}
$$

$$
\frac{\partial S_j^l(\Lambda^h_k, \Lambda^l_k, \mu_k)}{\partial \Lambda^l_k} \approx \frac{\tilde{S}^l_k(\Lambda^h_k, \Lambda^l_k + d\Lambda^l_k, \mu_k) - \tilde{S}^l_k(\Lambda^h_k, \Lambda^l_k - d\Lambda^l_k, \mu_k)}{2d\Lambda^l_k}
$$

$$
\frac{\partial S_j^l(\Lambda^h_k, \Lambda^l_k, \mu_k)}{\partial \mu} \approx \frac{\tilde{S}^l_k(\Lambda^h_k, \Lambda^l_k, \mu_k + d\mu_k) - \tilde{S}^l_k(\Lambda^h_k, \Lambda^l_k, \mu_k - d\mu_k)}{2d\mu}
$$

where $d\Lambda^h_k$, $d\Lambda^l_k$, and $d\mu_k$ (referred as step size) are the incremental change in arrival rate of high priority, arrival rate of low priority and service rate at hub $k$ respectively. Note that the symbols $\tilde{S}^l_k(.)$ denote the estimates of $S^l_k(.)$ obtained from numerical computations (using the matrix geometric method) for their corresponding parameter values. It is clear that we would conduct six computational runs to obtain these three estimates of subgradients at a point $(\Lambda^h_k, \Lambda^l_k, \mu_k)$ for every hub $k$ that is selected open ($z_{kk} = 1$). These estimates of subgradients are used to generate the constraints of the form (24).

3.5. Solution Algorithm

The linear model $[PL]$ with infinite number of constraints is amenable to an iterative cutting plane method, where the service level and its subgradients are estimated using matrix geometric method. It differs from the traditional description of the algorithm only in that we use matrix geometric method to evaluate the service level function and its subgradients due to the lack of existence of an algebraic expression for the function. The idea is to optimize a relaxed version of the problem by generating cuts from the violated service-level constraints and adding corresponding linear constraints until the optimal solution of the relaxed problem is feasible for the original problem. For that, we relax the service-level constraints (24), and solve the linear IP model to obtain an initial solution $(x^0, y^0, z^0)$. Using the flow allocation and the capacity level at the hubs, we compute the aggregate arrival rates $(\lambda^u_k)$ and service rates $(\mu_j)$ at all the hubs selected open. We then use matrix geometric method with the arrival rates and service rates obtained from the solution to get the estimates of service level function $S_j^l$ and its three subgradients. If these estimates satisfy the service-level constraints (24), then we stop with the optimal solution to model $[P]$, else we add a
set of linear constraints of the form (24) to the relaxed problem so that it will eliminate the current solution without eliminating any feasible solution. This procedure is repeated until all the service level constraints are satisfied. The convergence of this solution procedure can be proved along the lines of Atlason et al. (2004, 2008). The steps of the algorithm are summarized as follows:

**Algorithm 1 Cutting Plane Algorithm**

Ensure: $UB \leftarrow \infty; LB \leftarrow -\infty; q \leftarrow 0$
1: Solve $PL(H^q)$ without any service level constraints to obtain $(\pi^q, \chi^q, \beta^q)$ and $(\Lambda_k^{hq}, \Lambda_k^{hq}, \mu_k^q)$.
2: Compute service-level function $S_k^{hlq} (\Lambda_k^{hq}, \Lambda_k^{hl}, \mu_k^q)$ using the matrix geometric method.
3: while the service level constraint is not satisfied, i.e. $S_k^{hlq} (.) < \alpha_k$, do
4: Compute gradients of service-level function: $\frac{\partial S_k^{hlq}(.)}{\partial \Lambda_k^{hl}}, \frac{\partial S_k^{hlq}(.)}{\partial \mu_k}$, and $\frac{\partial S_k^{hlq}(.)}{\partial \mu_k}$.
5: Generate new constraints:

$$\frac{\partial S_k^{hlq}(.)}{\partial \Lambda_k^{hl}} \sum_i \sum_j \lambda_{ij} z_{ik} + \frac{\partial S_k^{hlq}(.)}{\partial \Lambda_k^{hl}} \sum_i \sum_j \lambda_{ij} z_{ik} + \frac{\partial S_k^{hlq}(.)}{\partial \mu_j} \sum_k \mu_{jk} y_{jk} \geq - \left\{ S_k^{hlq}(.) + \Lambda_k^{hq} \frac{\partial S_k^{hlq}(.)}{\partial \Lambda_k^{hl}} + \Lambda_k^{lh} \frac{\partial S_k^{hlq}(.)}{\partial \Lambda_k^{hl}} + \mu_k \frac{\partial S_k^{hlq}(.)}{\partial \mu_k} + \alpha^l \right\} z_{kk} \forall k, q \in Q$$

6: Append new constraints: $H^{q+1} \leftarrow H^q \cup \{ h_{new} \}$
7: $q \leftarrow q + 1$
8: Solve $PL(H^q)$ to obtain $(\pi^q, \chi^q, \beta^q)$ and $(\Lambda_k^{hq}, \Lambda_k^{hq}, \mu_k^q)$.
9: Compute service-level function $S_k^{hlq} (\Lambda_k^{hq}, \Lambda_k^{hl}, \mu_k^q)$ using the matrix geometric method.
10: end while

**4. Computational Results and Analysis**

In this section, we report the computational results and analysis with the proposed solution approaches and present some insights. The test problems are derived from U.S. Civil Aeronautics Board (CAB) data set (O’Kelly, 1987). The solution procedures were coded in C and the MIP problems were solved using CPLEX 11.2 on a Dell Intel Core PC with 2.40 GHz processor with 2 GB of RAM. The problems are solved to optimality (with an optimality gap of 10^-3).

**4.1. Sensitivity Analysis and Observations**

The sensitivity analysis is performed over an instance of CAB dataset with 15 Nodes and $p = 3$ hubs and the interdiscount factor $\beta$ of 0.2, 0.4 and 0.8. The average total flow rate/demand $\lambda_{ij}$ and the unit transportation cost $c_{ij}$ between each pair of nodes $(i, j)$ are obtained from the dataset. The collection and distribution cost coefficients are set to $\chi = \delta = 1$ per unit. For every potential hub, we generate three capacity levels - small (S), medium (M) and large (L), to choose from. The fixed costs are set to 150 (S), 200 (M) and 250 (L) and the capacity levels are set to $\frac{\text{Cap}}{p} + \beta \times A_l \times \text{Cap}$, where $\text{Cap} = \sum_i \sum_{j \neq k} \lambda_{ij}, k$ is the hub in a one-hub network with nodes which sends the least total flow, $p$ is the number of hubs to be opened, $\beta = 0.21, 0.22, 0.23, 0.24$ for 10, 15, 20, and 25 nodes respectively, $A_l$ is a constant.
that takes the value of -1, 0, and 1 for \( l = 1(S), 2(M), \) and 3(L) respectively. In all the test problems, we consider two customer classes - the mean demand arrival rate of the high priority (\( \lambda_{h}^{j} \)) and low priority (\( \lambda_{l}^{j} \)) priority customer is obtained by multiplying the total flow rate (\( \lambda_{ij} \)) by 0.60 and 0.40 respectively. The service level requirements are varied as shown in the table. The threshold on the target time \( W_{j} \) is set to expected waiting time in an M/M/1 queue: \( \min_{j} \{ \lambda_{j}/\mu_{j}(\mu_{j} - \lambda_{j}) + 1/\mu_{j} \} \), where \( \lambda_{j} = \lambda_{h}^{j} + \lambda_{l}^{j} \) and \( \mu_{j} \) are the arrival and service rates of the hubs selected open at the first iteration of the solution procedure (i.e. based on initial solution - \( x^{0}, y^{0} \)). In the implementation of the matrix geometric procedure, number of labels of high and low priority customer classes are set to \( M = 100 \). This is based on our initial tests that shows that as the value of \( M \) increases, the error introduced due to the truncation decreases, hence we set \( M = 100 \). The step size for estimating the subgradient using the finite difference method are set to: \( d\lambda_{h} = d\lambda_{l} = d\mu = 0.05 \).

In order to analyze the impact of target times (\( \tau_{h}, \tau_{l} \)) and service levels (\( \alpha_{h}, \alpha_{l} \)) on the configuration of the hub-and-spoke network, we conduct six set of experiments described as follows: (i) Effect of changing service level of single customer class (Table 1); (ii) Effect of changing target time of single customer class (Table 2); (iii) Effect of changing target time of high priority class (Table 3); (iv) Effect of changing target time of low priority class (Table 4); (v) Effect of changing service level of high priority class (Table 5); and (vi) Effect of changing service level of low priority class (Table 6). These tables report the total cost (TOTC), fixed cost (FC), transportation cost (TC), hubs locations and capacity level, the total high priority (\( \Lambda_{h} \)) and low priority (\( \Lambda_{l} \)) routed, as well as the number of iteration (ITR) and the computation time (CPU) of the algorithm. Plots in Figure 1 show the effect of increasing service level and decreasing target time on the total cost. Plots in Figure 2 show the effect of service level and target time of high and low priority class customers on the total costs. Our observations are as follows:

- The hub-and-spoke network configuration (hub locations, capacity selection, and allocation of nodes to hubs) that considers service-levels can be very different from the traditional configuration that ignores service-levels. Tables 1-6 shows the configuration of hub-and-spoke network for different values of service levels and target times. From these table, we observe that the network configuration i.e. hub location, their capacity levels, and the total flow through the hubs are different for different values of service levels and target times. For example, the optimal network with a discount factor of 0.2 and 85% service level has hubs 4, 12, and 13, where the model recommends opening hubs 1, 4, and 12 at 98% service level. As the service level increases to 99% service level, the hubs opened are 4, 6, and 7. Therefore, as the service level increases, the congestion decreases through the reallocation of non-hub nodes among the hubs in order to balance the flow through hubs to reduce hub utilization and congestion in the system. Although large hub capacity might seem a uneconomical decision for a firm at the beginning due to higher fixed costs, it can provide the firm with the competitive advantage of routing the flows in a timely and responsive manner, thereby guaranteeing higher service levels. This provides decision makers with the insight that the hub
location, capacity selection, and allocation/routing of flows are interrelated decisions and should be made in conjunction rather than isolation.

- **Substantial improvement in service level can be achieved with a small increase in total cost (transportation cost + fixed cost).** As can be seen from the plots in Figures 1 and 2 and the results in Tables 1, 5 and 6, as the service level increases, the total cost increases, however the increase in the total cost is marginal initially. Hence, substantial improvement in service level can be achieved with a small increase in total cost. This is because, as we increase the magnitude of service level, hubs with higher capacity level are utilized, flow gets distributed more evenly across hubs, average hub utilization decreases, thereby reducing overall congestion. This results in increase in service level.

- **Significant improvement in target time can be achieved with a small increase in total cost (transportation cost + fixed cost).** Plots in Figures 1 and 2 and the results in Tables 2, 3, and 4 indicate that as the target time decreases, the total cost increases, however the increase in the total cost is marginal initially. This is because, as we decrease the target time, the flow gets distributed more evenly across hubs, hubs with higher capacity level are utilized, the average hub utilization decreases, thereby reducing overall congestion at the hubs and improving service level. Hence, the decision maker should incorporate effects of service level in the model while designing such systems, to hedge against the variability in the flow.

![Graph showing the effect of changing service level and target time on the total cost.](image)

Figure 1: Effect of changing service level and target time on the total cost: The case of single customer class

5. Conclusion and Future Research

In this paper, we modelled and analyzed the effect of service-level constraints on the design of single allocation $p$-hub location problem. The model presented captures the tradeoff between the transportation cost savings induced by the economics of scale and the service level due to the variability of arrival rates of priority class customers and service rates of flow at hubs. Hubs are modelled as single server queues with Poisson arrivals and exponential service time distributions. The service level is measured using the number of customers served within a target time at hubs. For high priority class, we present a matrix geometric approach to evaluate the service-level constraints. Under concavity assumption, we linearize
the model and use an cutting plane algorithm based procedure. In order to mitigate the effect of congestion and meet the service level constraints, the model prescribes redistribu-

Utilization of flow across the hubs to achieve more even hub utilization and/or the location of hubs with larger capacity to achieve higher relative difference of total flow through hub and its capacity. We used the models to demonstrate that substantial improvement in service level constraints can be achieved with a small increase in total costs associated with designing such networks. Also, we illustrated that the configuration of the hub-and-spoke network (hub location and capacity, and allocation of nodes to hubs) obtained using the model can be very different from those obtained using the traditional models that ignores service-levels. Our computational experiments also reveal that the cutting plane algorithm with matric geometric method proved to be an efficient solution procedure for finding the optimal solution to the problem in reasonable computation time.

There are many future research avenues for extending the queueing-based service-level...

modelling framework. One of them is to extend the framework to other hub location formulation such as multiple allocation hub location models, p-center hub location models and hub covering models. Another promising avenue that can be explored is to extend the queuing-based service-level modelling framework to deal with congestion on links (and link capacity selection) in the hub-and-spoke network. One can also explore the use of embedding the proposed cutting plane based solution procedure within the Lagrangean relaxation/Benders decomposition framework to solve large-scale instances of problems.
