#### Abstract

Our data, relating to a period of extreme market turmoil, show typical leptokurtosis and skewness, leading us to consider the skewed exponential power distribution of Fernández et al. (1995), referred to as the SEP3. We demonstrate that the conditional forecasting of VaR and CVaR, made up of a mixture of two SEP3 densities, can efficiently cover market risk at regulatory levels of $1 \%$ and $2.5 \%$, as well as at the additional $5 \%$ level. The SEP3 mixture outcomes are benchmarked using a variety of competing models, including the generalized Pareto distribution. Appropriate scoring functions help focus quickly on valuable models, which should undergo five conventional backtests. As a sixth backtest, we argue for and apply the CVaR part of the optimality test of Patton et al. (2019) to assess the conditional adequacy of CVaR. Various additional statistical approaches are employed to validate models in response to Basel recommendations. We propose a novel criterion for CVaR accuracy assessment, based on its positioning in relation to the empirical CVaR- and CVaR+. An additional aim of this paper is to present a collaborative framework that relies on both comparative and conventional backtesting tools, all in compliance with the recent Basel regulation for market-risk.

Keywords: Conditional forecasting, VaR, CVaR, Backtesting, basel regulation for market risk, heavy tailed distributions.

## Highlights

- Conditional forecasting of VaR and CVaR , using a mixture of the skewed exponential power distribution.
- Testing the conditional adequacy of CVaR.
- In line with Basel 2019, performing required and supplementary VaR and CVaR evaluations.
- Backtesting conclusion tied to empirical model performance.
* The authors thank Claire Boisvert for her collaboration in the preparation of the manuscript.

## Introduction

In 2016, the Basel Committee decided that banks' market risk capital should be calculated with the conditional value at risk (CVaR), also known as expected shortfall, ${ }^{1}$ at the $97.5 \%$ confidence level, while maintaining model backtesting at the $99 \%$ value at risk (VaR) (BCBS, 2016, 2019). This shift toward CVaR is motivated by issues of consistency and by the inadequacy of the risk coverage calculated by VaR, which has been noted over time. Market risk is now jointly managed via CVaR and VaR, at two different probabilities: $\mathrm{p}=2.5 \%$ and $\mathrm{p}=1 \%$, respectively. ${ }^{2}$

In recent decades, it has become increasingly important to assess financial risk accurately; selecting a suitable distribution has turned out to be a major challenge. The empirical evidence against normality is considerable (see, e.g., Haas et al., 2006). Accounting for heavy tails, autocorrelations, and volatility clustering, the stylized aspect of financial time series is more critical than ever for gauging market risk (McNeil et al., 2015).

On the one hand, for these reasons, various methods to transform normal density, such as Gram-Charlier expansions, have been created to meet the desired features, for increased flexibility in fitting empirical distributions (see, e.g., Zoia et al., 2018; Molina-Muñoz et al., 2021). On the other hand, alternative distributions to replace Gaussian law have been studied, including stable distributions and several Student- $t$ extensions (see, e.g., Lee and Lin, 2012; Iqbal et al., 2020). A great deal of effort is also being made based on exponential power (EP) distribution, which, with three parameters, can reproduce any kurtosis level. Fernández et al. (1995) introduce a fourparameter skewed EP, which will be abbreviated as SEP3 density here. Zhu and Zinde-Walsh (2009) present a five-parameter asymmetric exponential power distribution (AEPD) that captures both the right- and left-tail thicknesses independently. Downside risk measurement and forecasting accuracy improve when the relevant tail is more adequately captured. Zhu and Galbraith (2011) and, more recently, Kim and Lee (2021) use AEPD to build a conditional heteroscedastic specification.

[^1]Earlier, Rombouts and Bouaddi (2009) showed that a mixture of a skewed construction using an EP distribution worked properly to model standardized innovations in an asymmetric GARCH-type model. Indeed, a distribution mixture is an interesting alternative, offering a degree of freedom to represent the left and right tails relatively separately in terms of skewness and tail thickness. It is in this line that we link our work.

We propose to show that a mixture of two SEP3 works well for conditional forecasting with two stages, as in McNeil and Frey (2000) and as shown in Nolde and Ziegel (2017), the latter of which we refer to as NZ (2017) in the sequel. The first stage, based on an $\operatorname{AR}(1)-\operatorname{GARCH}(1,1)$, will model the standardized innovations in two ways: a Gaussian and the Skew- $t$ of Fernández and Steel (1998). For the second stage, to gradually develop and document the outcomes, we will first take an exploratory approach in Section 3, starting with a simple normal law and moving on to a SEP3 mixture, through other competing models with either single distributions or mixtures.

To measure risk, we focus on VaR, well-known and elicitable, and CVaR, a coherent and additive risk measure. Let Y represent the return on a given asset over a given horizon. Negative returns, which are subject to loss risk, are located at the left tail of the $Y$ distribution. Also, p-levels are small, close to 0 . At a given $\mathrm{p}-\mathrm{level} \in(0,1), \mathrm{p}-\mathrm{VaR}$ is defined by

$$
\operatorname{VaR}^{\mathrm{p}}(\mathrm{Y})=-\inf \left\{\mathrm{y} \mid \mathrm{F}_{\mathrm{Y}}(\mathrm{y}) \geq \mathrm{p}\right\}
$$

where $\mathrm{F}_{\mathrm{Y}}$ is the cumulative function of $\mathrm{Y} . \mathrm{p}-\mathrm{VaR}$ can also be defined as the absolute value of Y 's p-quantile. CVaR is the absolute value of the expected return Y conditional on Y being below the p-quantile of $Y$. Assuming $F_{Y}$ strictly increases with finite mean, $p-C V a R$ is defined by

$$
\operatorname{CVaR}^{\mathrm{p}}(\mathrm{Y})=-\mathrm{E}\left[\mathrm{Y} \mid \mathrm{Y}<-\operatorname{VaR}^{\mathrm{p}}\right]
$$

Due to our convention, VaR and CVaR are positive; the greater the value, the riskier the situation being measured. Assuming normal returns, $2.5 \%-\mathrm{CVaR}$ represents a risk similar to $1 \%-$ VaR.

As secondary risk measures, we will employ the empirical VaR, CVaR-, and CVaR+ (Rockafellar and Uryasev, 2002). Similarly, the empirical VaR is the absolute value of the empirical p-quantile. $\mathrm{CVaR}-(\mathrm{CVaR}+)$ is the absolute value of the empirical expected return
conditional on the return falling below and including (excluding) the empirical p-quantile of a possibly discontineous or discrete distribution (see Section 2 for details).

In addition to the regulatory requirements for capital, the new Basel regulations strongly recommend supplementing statistical procedures to ensure the ex-post suitability of models (BCBS, 2016, page 82; BCBS, 2019, paragraph 32.13). For these reasons, the models must be validated in three steps. First, we use conventional tools measuring goodness-of-fit. As a second step, we let ourselves be guided by the model moments, skewness, and kurtosis coefficients, compared to the empirical measures of the sample. We also explore a novel criterion seeking to compare model-derived CVaR to the empirical CVaR-and CVaR + measurements. The purpose of steps 1 and 2 is to provide a quick and interesting overview of model behaviors before going deeper.

For steps 1 and 2, the parametric models are fitted to sample data in pure (unconditional) modeling. By contrast, step 3 is dedicated to conditional VaR and CVaR forecasting. Models are evaluated through a collaborative approach using tools from both branches of backtesting: conventional (called standard) and comparative. Depending on level $\mathrm{p}=1 \%$ or $2.5 \%$, appropriate scoring functions guide the analysis to focus on worthwhile models, whereas models are validated individually using standard backtests and on the basis of the DM test (Diebold and Mariano, 1995).

Three standard VaR tests are applied: the uc test of Kupiec (1995), cc of Christoffersen (1998), and DQ of Engle and Manganelli (2004). For CVaR, we use the $Z_{E S}$ test of Acerbi and Szekely (2019) and the RC test of Righi and Ceretta (2015). Moreover, we argue for and employ the CVaR part of the optimality test of Patton et al. (2019) to evaluate the CVaR's conditional adequacy. One aim of this paper is to orchestrate all these aspects into a validation process that complies with the regulations in force.

We utilize a sample of data from three assets: IBM, General Electric, and Walmart, whose returns all refute normality over the time period under examination, which encompasses the extreme price fluctuations of the last economic recession in the United States (NBER ${ }^{3}$ December 2007 to June 2009) and the financial crisis of August 2007 to February 2009 (TED spread). Our

[^2]competing models have a role to play in identifying and documenting specific aspects of the research. Due to their well-known performance at high quantiles, the generalized Pareto distribution (GP, McNeil et al. 2015) and the exponential generalized beta type 2 (EGB2, Kerman and McDonald, 2015) are also in the running to benchmark the findings.

We provide mathematical derivations of VaR and CVaR for our parametric models in the Online Appendices. Appendix A1 describes the model naming. Appendices A2 and A3 derive formulas to compute CVaR for distribution mixtures, while Appendices A4 to A10 derive the CVaR formula for individual parametric distributions. With the aforementioned assets, we design in Appendix A11 an optimal portfolio, which will serve as input data beginning in Section 3.

The first section, which follows, presents the data. Section 2 provides a preliminary analysis. Section 3 establishes an initial unconditional modeling. Section 4 presents the conditional forecasting and backtesting framework. Section 5 covers backtesting results. The final section discusses the results and concludes the paper.

## 1. Data

Our data contains three risky stocks: IBM, General Electric, and Walmart. The period consists of 1,200 days, from June 18, 2007, to March 20, 2012. The actual daily price extraction period starts 251 days earlier, on June 16, 2006. In total, 1,451 daily prices are collected $(=1,200+250+1$ day $)$, to provide 250 -day rolling windows for the out-of-sample framework, plus one additional day to compute the first day's return.

Figure 1 shows that, over the period in question, the asset return distributions are far from normal. By fitting a Student- $t$ distribution to the returns, using the standard maximum likelihood approach, the estimated degrees of freedom are 3.2, 2.4, and 3.2, respectively, indicating the presence of a very fat tail.

Figure 1: Histograms and densities of IBM, GE, and WM stocks

Table 1 displays descriptive statistics, including a correlation matrix. During this period of the financial crisis, the correlations are all positive and very strong, at around $50 \%$.

Table 1 Descriptive statistics of individual assets

|  | IBM | General Electric | Walmart |
| :--- | :--- | :--- | :---: |
| Correlations |  |  |  |
| IBM | 1 |  |  |
| General Electric | 0.56759 | 1 | 1 |
| Walmart | 0.49146 | 0.43083 |  |
| Covariances* |  |  | 0.01138 |
| IBM | 0.02688 | 0.02443 | 0.01598 |
| General Electric | 0.02443 | 0.06894 | 0.01995 |
| Walmart | 0.01138 | 0.01598 | $0.03472 \%$ |
| Mean | $0.07580 \%$ | $-0.00286 \%$ | 0.01995 |
| Variance* | 0.02688 | 0.06894 | 0.35429 |
| Skewness | 0.27190 | 0.35375 | 10.68244 |
| Kurtosis | 7.43415 | 9.95718 |  |

[^3]On average, the daily returns are practically nil. The skewness coefficients are positive, which is surprising given that the extreme market turmoil should instead cause a shift toward the left tail of losses. The empirical kurtosis coefficients are very large, roughly three times higher than the known normal of 3 . This confirms the presence of a large tail thickness.

## 2. Preliminary analysis

Let $Y_{t}$ be the return on the given asset over a time horizon $t . Y_{t}$ follows a distribution F , assumed strictly increasing with finite mean. At a given p-level, we have

$$
\begin{gather*}
\operatorname{VaR}^{p}=-\mathrm{F}^{-1}(\mathrm{p})  \tag{1}\\
\mathrm{CVaR}^{\mathrm{p}}=-\mathrm{E}\left[\mathrm{Y}_{\mathrm{t}} \mid \mathrm{Y}_{\mathrm{t}}<-\operatorname{VaR}^{\mathrm{p}}\right] . \tag{2}
\end{gather*}
$$

Following Rockafellar and Uryasev (2002), the empirical VaR, $\mathrm{CVaR}^{-}$, and $\mathrm{CVaR}^{+}$ measures of data, are defined by

$$
\begin{equation*}
\mathrm{CVaR}^{+}=-\mathrm{E}\left[\mathrm{Y}_{\mathrm{t}} \mid \mathrm{Y}_{\mathrm{t}}<-\mathrm{VaR}\right] \text { and } \mathrm{CVaR}^{-}=-\mathrm{E}\left[\mathrm{Y}_{\mathrm{t}} \mid \mathrm{Y}_{\mathrm{t}} \leq-\mathrm{VaR}\right] \tag{3}
\end{equation*}
$$

which can be computed by

$$
\begin{equation*}
\mathrm{CVaR}_{\mathrm{np}}^{+}=-\frac{1}{\mathrm{~N}_{\mathrm{T}}^{+}} \sum_{\mathrm{t}=1}^{\mathrm{T}} \mathrm{Y}_{\mathrm{t}} \times\left(\mathrm{Y}_{\mathrm{t}}<-\mathrm{VaR}_{\mathrm{np}}\right) \text { and } \mathrm{CVaR}_{\mathrm{np}}^{-}=-\frac{1}{\mathrm{~N}_{\mathrm{T}}^{-}} \sum_{\mathrm{t}=1}^{\mathrm{T}} \mathrm{Y}_{\mathrm{t}} \times\left(\mathrm{Y}_{\mathrm{t}} \leq-\mathrm{VaR}_{\mathrm{np}}\right) \tag{4}
\end{equation*}
$$

where

$$
\begin{equation*}
\operatorname{VaR}_{\mathrm{np}}=- \text { Quantile }\left(\mathrm{Y}_{\mathrm{t}}, \mathrm{p}\right) . \tag{5}
\end{equation*}
$$

$\mathrm{N}_{\mathrm{T}}^{+}=\sum_{\mathrm{t}=1}^{\mathrm{T}} 1 \times\left(\mathrm{Y}_{\mathrm{t}}<-\mathrm{VaR}_{\mathrm{np}}\right) ; \mathrm{N}_{\mathrm{T}}^{-}=\sum_{\mathrm{t}=1}^{\mathrm{T}} 1 \times\left(\mathrm{Y}_{\mathrm{t}} \leq-\mathrm{VaR}_{\mathrm{np}}\right)$. For $\mathrm{p}=5 \%, \operatorname{VaR}_{\mathrm{np}}$ is the absolute value of the 61st smallest value of $Y_{t}$. The subscript $n p$ indicates nonparametric empirical estimates throughout the sequel.

Using the three assets, we construct an optimal portfolio $\mathrm{Y}_{\mathrm{t}}^{*}$. The optimal weight vector is $\beta=(0.3889,-0.0465,0.6575)$; for detailed calculations, see Appendix A11. To simplify the notations, we will continue to refer to this optimal portfolio as $Y_{t}$ in the following.

Table 2 displays the optimal portfolio's computed $\mathrm{VaR}_{\mathrm{np}}, \mathrm{CVaR}_{\mathrm{np}}^{-}$, and $\mathrm{CVaR}_{\mathrm{np}}^{+}$alongside those of the individual assets. Portfolio $\mathrm{VaR}_{\mathrm{np}}=2.047 \%$, whereas the weighted sum, representing holding $\beta$-proportions of the assets separately, shows a $\operatorname{VaR}_{n p}=2.573 \%$ (no correlations). Difference column reveals that holding an optimal portfolio is less risky by about 52.5 basis points (diversification principle). The same pattern applies to $\mathrm{CVaR}_{\mathrm{np}}^{-}$and $\mathrm{CVaR}_{\mathrm{np}}^{+}$lines.

We now compute the relative range $\left(\mathrm{CVaR}_{\mathrm{np}}^{+} / \mathrm{CVaR}_{\mathrm{np}}^{-}\right)-1=2.978 / 2.963-1 \approx 0.51 \%$, which is extremely small. As such, being within, or not too far from, the $\left[\mathrm{CVaR}_{\mathrm{np}}^{-}, \mathrm{CVaR}_{\mathrm{np}}^{+}\right]$range becomes a distinguishing characteristic. We will see in Section 3 how models behave in this regard.

Figure 2 clearly shows that a Gaussian cannot fit. Student- $t$ is not sharp enough and does not keep enough mass around the mode. This rather suggests a Laplace density.

Table 2
Empirical measurements of VaR, CVaR-, and CVaR+

|  |  | IBM | GE | Walmart |  |  |
| :--- | ---: | :---: | :---: | :---: | :---: | :---: |

## 3. Unconditional estimations

The return portfolio $Y_{t}$ is assumed to remain optimal for all competing models, to ensure result comparability. Models M1 through M8 are directly fitted to $\left\{\mathrm{Y}_{\mathrm{t}}\right\}_{\mathrm{t}=1}^{1200}$ using the maximum likelihood approach in static modeling (see next sections for conditional modeling).

Step 1 of the model validation consists of the usual criteria: AIC, BIC, and the KS goodness-of-fit test. In step 2, model-derived kurtosis and asymmetry coefficients are compared to empirical ones. We also present a novel empirical criterion for assessing derived CVaR accuracy. According to Rockafellar and Uryasev (2002), the empirical CVaR is framed by its related measures: $\mathrm{CVaR}^{-}$ and $\mathrm{CVaR}^{+}$. As a natural outcome, we argue that a successful derived CVaR should also obey the same framing: $\mathrm{CVaR}^{-} \leq \mathrm{CVaR}_{\text {model }} \leq \mathrm{CVaR}^{+}$.

Tables 3 and 4 depict results for $\mathrm{p}=5 \%$. For mixtures, $\mathrm{c}_{\mathrm{j}}$ identifies the weight of the $\mathrm{j}^{\text {th }}$ individual density in the mixture. Empirical $\mathrm{VaR}_{\mathrm{np}}=2.047 \%$ and interval $\left[\mathrm{CVaR}_{\mathrm{np}}^{-}, \mathrm{CVaR}_{\mathrm{np}}^{+}\right]=[2.962 \%, 2.977 \%]$, abbreviated by $\mathrm{C}_{-}^{+}$, are from Table 2. We take a look at the salient features to provide a quick overview of model traits before going deeper into it in Sections 4 and 5.

Our first model, M1 $=1$ :NO, consists of a single Gaussian (Appendix A4). Obviously, M1 is far from allowing the targeted empirical skewness $=0.35$ and kurtosis $=9.81$. The next model, M2, assumes a single Student- $t$ (Appendix A5). The estimated degree of freedom $v=3.288<4$ confirms a high tail thickness. $\mathrm{CVaR}>\mathrm{C}_{-}^{+}$range. KS does not reject M2. AIC and BIC improve compared to M1, but asymmetry cannot be captured. M3 $=1$ : EGB2 has a single EGB2 density (exponential generalized beta 2; Appendix A6). Both thickness and skewness can be captured by $v$ and $\tau$. Values $v=0.165$ and $\tau=0.158$ tend to 0 . Therefore, EGB2 tends toward a Laplace (Lemma 2 of Caivano and Harvey, 2014). This confirms Section 1 remarks.

We now explore density mixtures. $\mathrm{M} 4=2: \mathrm{NO}$ is made of two normals (Appendices A2, A3, A4). Kurtosis $=6.7$ improves. $\mathrm{KS} p$-value $=0.218>10 \%$. However, $\mathrm{CVaR}=3.113 \%$ is the farthest away from $\mathrm{C}_{-}^{+}$. Next is M5 = $2: \mathrm{T}$, a two Student $-t$ mixture (Appendices A2, A3, and A5). Kurtosis of 8.4 is close to 9.8. $\mathrm{BIC}=-7,207.6$ deteriorates. $\mathrm{VaR} \approx \mathrm{VaR}_{\mathrm{np}}$ but $\mathrm{CVaR}=3.041 \%>\mathrm{C}_{-}^{+}$. A word about M6=3:NO (three normals), which almost reaches empirical kurtosis: $9.4 \approx 9.8 . \operatorname{VaR} \approx \mathrm{VaR}_{\mathrm{np}}$ and $\mathrm{CVaR}=3.004 \%$ is close to $\mathrm{C}_{-}^{+}$. However, it cannot capture data skewness.

To capture data skewness, we build $\mathrm{M} 7=2$ : SN2, which is a two SN 2 mixture (skewed normal type 2 of Fernández et al., 1995, Appendix A7). Both skewness parameters, $v_{1} \approx 1.44>1$ and $v_{2} \approx 1.10>1$, comply with the data. Although kurtosis and AIC deteriorate, the good news is that $\mathrm{CVaR}=2.968 \%$ falls inside $\mathrm{C}_{-}^{+}$. We probably have our first noteworthy model.

We now incorporate tail thickness, using two SEP3 distributions (skewed exponential power type 3 of Fernández et al., 1995). M8=2:SEP3 has nine parameters (Appendices A3, A8, and A9).

AIC and BIC indicate a better fit to the data. $\operatorname{VaR}=1.992 \% \leq \operatorname{VaR}_{\mathrm{np}}$, but, interestingly, its $\mathrm{CVaR}=2.973 \%$ falls inside $\mathrm{C}_{-}^{+}$.

Based on thickness and skewness parameters $\tau_{1}=0.959 \approx 1, v_{1}=1.031 \approx 1, \tau_{2}=2.108 \approx 2$, and $v_{2}=0.613<1$, the first SEP3 is a Laplace degenerate, whereas the second SEP3 is practically an asymmetric normal, which is an SN2. These facts illustrate relationships between our models. The results corroborate similar findings in the recent market-risk literature highlighting the Laplace-Gaussian mixture (Haas, 2009; Broda and Paolella, 2011; Miao et al., 2016).

For further analysis, Tables 3 and 4 provide exhaustive information. Also, Table A. 3 (Online Appendices) illustrates the behavior of the eight models at $\mathrm{p}=2.5 \%$ and $1 \%$, which is similar to $\mathrm{p}=5 \%$.

To conclude this overview section, Figure 3 depicts VaR and CVaR behaviors in the left tail for 2:SEP3 along with 1:NO and 1:T, including their densities. Risk measures are reported negatively, so they can be shown with negative returns.

## 4. Out-of-sample forecasting and backtesting

### 4.1 Conditional modeling

In contrast to Section 3, we are now interested in VaR and CVaR conditional forecasting, with an out-of-sample framework based on 250 -day rolling windows. The purpose is to capture time dynamics to account for autocorrelations and conditional volatility, including volatility clustering, which are typically observed in financial series of market risk (McNeil et al., 2015). The return series $Y_{t}$ now follows a conditional distribution $F_{t}: Y_{t} \mid \mathfrak{J}_{t-1} \sim F_{t}$, where $\mathfrak{I}_{t-1}$ is the information set available up to $\mathrm{t}-1$. With the usual assumptions, conditional risk measures at p level are defined by

$$
\operatorname{VaR}_{\mathrm{t}}^{\mathrm{p}}=-\mathrm{F}_{\mathrm{t}}^{-1}(\mathrm{p}) \text { and } \mathrm{CVaR}_{\mathrm{t}}^{\mathrm{p}}=-\mathrm{E}_{\mathrm{t}-1}\left[\mathrm{Y}_{\mathrm{t}} \mid \mathrm{Y}_{\mathrm{t}}<-\operatorname{VaR}_{\mathrm{t}}^{\mathrm{p}}\right] .
$$

Following NZ (2017), assume that $Y_{t}$ can be written as

$$
\begin{equation*}
\mathrm{Y}_{\mathrm{t}}=\mu_{\mathrm{t}}+\sigma_{\mathrm{t}} \mathrm{Z}_{\mathrm{t}} \tag{6}
\end{equation*}
$$

where $Z_{t}$ is an i.i.d. random standardized variable. $\mu_{t}=E\left[Y_{t} \mid \Im_{t-1}\right]$ and $\sigma_{t}^{2}=\operatorname{var}\left[\mathrm{Y}_{\mathrm{t}} \mid \mathfrak{I}_{\mathrm{t}-1}\right]$ are the conditional expectation and conditional variance at $t$ given $\mathfrak{J}_{\mathrm{t}-1}$. The conditional risk measures of $\left\{Y_{t}\right\}$ for $t+1$ can be obtained from those of $\left\{Z_{t}\right\}$ using the same linear combination (6) and with one-step ahead predicted $\mu_{t+1}$ and $\sigma_{t+1}$

$$
\begin{equation*}
\operatorname{VaR}_{t+1}^{p}\left(Y_{t}\right)=\mu_{t+1}+\sigma_{t+1} \operatorname{VaR}_{t+1}^{p}\left(Z_{t}\right) \text { and } \operatorname{CVaR}_{t+1}^{p}\left(Y_{t}\right)=\mu_{t+1}+\sigma_{t+1} \operatorname{CVaR}_{t+1}^{p}\left(Z_{t}\right) \tag{7}
\end{equation*}
$$

An ARMA-GARCH specification allows for such a design. We will use an $\operatorname{AR}(1)-\operatorname{GARCH}(1,1)$ to model $\mu_{\mathrm{t}}($ eq. 8$)$ and $\sigma_{\mathrm{t}}($ eq. 9$)$. The $\operatorname{AR}(1)-\operatorname{GARCH}(1,1)$ system is written as

$$
\begin{gather*}
\mathrm{y}_{\mathrm{t}}=\xi_{0}+\xi_{1} \mathrm{y}_{\mathrm{t}-1}+\varepsilon_{\mathrm{t}}  \tag{8}\\
\sigma_{\mathrm{t}}^{2}=\omega+\delta_{1} \varepsilon_{\mathrm{t}-1}^{2}+\delta_{2} \sigma_{\mathrm{t}-1}^{2}  \tag{9}\\
\mathrm{z}_{\mathrm{t}}=\varepsilon_{\mathrm{t}} / \sigma_{\mathrm{t}} ; \quad \mathrm{Z}_{\mathrm{t}} \sim \mathrm{G}(\theta) \tag{10}
\end{gather*}
$$

where $\left(\xi_{0}, \xi_{1}, \omega, \delta_{1}, \delta_{2}, \theta\right)$ are the $\operatorname{AR}(1)-\operatorname{GARCH}(1,1)$ parameters. The error term $\varepsilon_{t}$, once standardized, supplies $Z_{t}$ such as $Z_{t}=\varepsilon_{t} / \sigma_{t} . Z_{t}$ follows a distribution $G$, whose parameters $\theta$ ensure zero mean and unit variance. If $G$ is known, $\operatorname{AR}(1)-\operatorname{GARCH}(1,1)$ can be estimated by the maximum likelihood method. We then derive

$$
\begin{gather*}
\mu_{t+1}=\mathrm{E}\left[\mathrm{Y}_{\mathrm{t}+1} \mid \mathfrak{I}_{\mathrm{t}}\right]=\xi_{0}+\xi_{1} \mathrm{y}_{\mathrm{t}}  \tag{11}\\
\sigma_{\mathrm{t}+1}^{2}=\operatorname{var}\left[\mathrm{Y}_{\mathrm{t}+1} \mid \mathfrak{J}_{\mathrm{t}}\right]=\omega+\delta_{1}\left(\sigma_{\mathrm{t}} \mathrm{z}_{\mathrm{t}}\right)^{2}+\delta_{2} \sigma_{\mathrm{t}}^{2} \tag{12}
\end{gather*}
$$

and finally calculate risk measures related to G. In the real world, however, G is unknown. So, we proceed in two stages: In the first, identified as prefiltering, we impose a distribution on G (usually a normal, a Student- $t$ or a Skew- $t$ distribution). We then estimate $\left(\xi_{0}, \xi_{1}, \omega, \delta_{1}, \delta_{2}, \theta_{t}\right)$ using the 250-day rolling window $\left\{\mathrm{Y}_{\mathrm{s}}\right\}_{\mathrm{s}=\mathrm{t}-249}^{\mathrm{s}=\mathrm{t}}$. Meanwhile, the prefiltering stage suffers from a misspecification introduced by imposing an arbitrary distribution on unknown G .

Our competing models come into play in the second stage, which we henceforth call fitting. The models can more or less effectively recover the gaps due to the aforementioned misspecification. Models fitted to $Z_{t}$ produce $\operatorname{VaR}_{t+1}^{p}\left(Z_{t}\right)$ and $\operatorname{CVaR}_{t+1}^{p}\left(Z_{t}\right)$, which are converted back to $\operatorname{VaR}_{t+1}^{p}\left(Y_{t}\right)$ and $\operatorname{CVaR}_{t+1}^{p}\left(Y_{t}\right)$ by applying the forecasted $\mu_{t+1}$ and $\sigma_{t+1}$ using (11) and (12) into equalities (7).

There will be two prefilterings. The first, denoted $n$-prefiltering, forces $G$ to follow a Gaussian, whereas the second, called e-prefiltering, imposes the Skew- $t$ of Fernández and Steel (1998).

This Skew- $t$ distribution, named ST3, has four parameters, say, $\mu, \sigma, \nu, \tau$, and its density function is written for $x \in R$, such that

$$
\begin{equation*}
\mathrm{f}_{\mathrm{ST3}}(\mathrm{x} \mid \mu, \sigma, v, \tau)=\frac{\mathrm{c}}{\sigma}\left\{\left[1+\frac{v^{2} \mathrm{u}^{2}}{\tau}\right]^{-(\tau+1) / 2} 1_{\mathrm{y}<\mu}+\left[1+\frac{\mathrm{u}^{2}}{v^{2} \tau}\right]^{-(\tau+1) / 2} 1_{\mathrm{y} \geq \mu}\right\} \tag{13}
\end{equation*}
$$

where $u=(x-\mu) / \sigma ; \quad \mu \in R ; \quad \sigma, v, \tau>0$, and $c=2 v\left[\left(1+v^{2}\right) B(1 / 2, \tau / 2) \tau^{1 / 2}\right]^{-1}$.

We add a prefix n or e to properly specify the conditional models. Thus, the 3 :NO basic model (Section 3) will correspond to two conditional models: $\mathrm{n} \mid 3: \mathrm{NO}$ (n-prefiltered) and e $\mid 3: \mathrm{NO}$ (e-prefiltered). Likewise, e|1:T is based on a single Student- $t$ distribution fitted to $Z_{t}$ series obtained from e-prefiltering.

Three new basic models are required. The first, $\mathrm{M} 9=1: \mathrm{ST} 3$, (single Skew- $t$ density) is related to the conditional model e 1 :ST3, which will benchmark e-prefiltered models because it has ST3 in both stages. The predictive power of the resulting conditional model is expected to be average or poor when the same density is arbitrarily forced in both stages (see NZ, 2017). M10 $=1$ :SEP3 is the second basic model (single SEP3 density). The conditional model $\mathrm{e} \mid 1: \operatorname{SEP} 3(\mathrm{n} \mid 1:$ SEP3) will serve to identify the mixture effect on e|2:SEP3(n|2:SEP3) performance (see discussion later).

We define a final model, M11, which estimates the well-known generalized Pareto distribution (GP) in the fitting stage. GP is frequently needed to challenge the ability of studied models to account for extreme values in the data. Return series will be momentarily negated to fit GP. For a threshold $u$ and $\mathrm{y} \geq \mathrm{u}$, the cumulative function of GP is written as

$$
\mathrm{F}_{\mathrm{GP}}(\mathrm{x})=1-\left(1+\xi \frac{\mathrm{y}-\mathrm{u}}{\beta}\right)^{-1 / \xi} \xi \neq 0
$$

where $\beta$ and $\xi$ are the scale and shape parameters of GP. The threshold $u$ must be determined. We use pragmatic method of McNeil and Frey (2000) and, like NZ (2017), we fit GP to the 30 largest values from the 250 -day rolling window; $u_{t}$ is the $31^{\text {st }}$ largest value ( $30=12 \%$ of 250 ). Finally, the formulas are as follows:

$$
\operatorname{VaR}_{t}^{p}=u_{t}+\frac{\beta_{t}}{\xi_{t}}\left(\left(\frac{p}{N_{u} / N_{w}}\right)^{-\xi_{t}}-1\right) \quad \text { and } \quad \operatorname{CVaR}_{t}^{p}=\frac{\operatorname{VaR}_{t}^{p}}{1-\xi_{t}}+\frac{\beta_{t}-u_{t} \xi_{t}}{1-\xi_{t}}
$$

where $\left(\mathrm{u}_{\mathrm{t}}, \beta_{\mathrm{t}}, \xi_{\mathrm{t}}\right)$ parameters correspond to day $t$ fitted GP; $\mathrm{N}_{\mathrm{u}}=30, \mathrm{~N}_{\mathrm{w}}=250$.

In total, we have 22 conditional models (11 for each prefiltering).

### 4.2. Standard backtesting

## VaR testing

### 4.2.1. Unconditional coverage test

Unconditional coverage testing is based on the fact that counting independent $\mathrm{p}-\mathrm{VaR}$ violations follows a binomial distribution. With T and $\mathrm{N}_{1}$ denoting time length and number of violations, respectively, Kupiec's (1995) test compares $\mathrm{p}^{*}=\mathrm{N}_{1} / \mathrm{T}$ (failure rate) to p (theoretical rate) with a likelihood ratio test. The null hypothesis is $\mathrm{H}_{0}: \mathrm{p}^{*}=\mathrm{p}$ against $\mathrm{H}_{1}: \mathrm{p}^{*} \neq \mathrm{p}$. The test statistic $\mathrm{LR}_{\text {uc }}$ is

$$
\begin{equation*}
\mathrm{LR}_{\mathrm{uc}}=-2 \log \left[\frac{(1-\mathrm{p})^{\mathrm{T}-\mathrm{N}_{1}} \mathrm{p}^{\mathrm{N}_{1}}}{\left(1-\mathrm{N}_{1} / \mathrm{T}\right)^{\mathrm{T}-\mathrm{N}_{1}}\left(\mathrm{~N}_{1} / \mathrm{T}\right)^{\mathrm{N}_{1}}}\right] \sim \chi_{\mathrm{df}=1}^{2} \tag{14}
\end{equation*}
$$

which asymptotically follows a chi-square distribution with one degree of freedom.

### 4.2.2. Independence test

Violations of $\mathrm{p}-\mathrm{VaR}$ should be independent and well dispersed in time. The occurrence of violation clustering may result in the inability to renew coverage capital in time. Christoffersen (1998) considers the violation process $I_{t}$ as first-order Markovian with two states. Its transition matrix, $\Pi$, is

$$
\Pi=\left[\begin{array}{ll}
1-\pi_{01} & \pi_{01}  \tag{15}\\
1-\pi_{11} & \pi_{11}
\end{array}\right]
$$

where $\pi_{\mathrm{ij}}$ is the transition probability from state $i$ to state $j$. The process likelihood is

$$
\begin{equation*}
\mathrm{L}(\Pi)=\left(1-\pi_{01}\right)^{\mathrm{N}_{00}} \pi_{01}^{\mathrm{N}_{01}}\left(1-\pi_{11}\right)^{\mathrm{N}_{10}} \pi_{11}^{\mathrm{N}_{11}} \tag{16}
\end{equation*}
$$

where $\mathrm{N}_{\mathrm{ij}}$ is the number of observations with a state $j$ following a state $i$. There is violation independence if $H_{0}: \pi_{01}=\pi_{11}$. $L(\Pi)$ can be estimated empirically by $L(\hat{\Pi})$, where $\pi_{01}$ and $\pi_{11}$ are replaced by $\hat{\pi}_{01}=\mathrm{N}_{01} /\left(\mathrm{N}_{00}+\mathrm{N}_{01}\right)$ and $\hat{\pi}_{11}=\mathrm{N}_{11} /\left(\mathrm{N}_{10}+\mathrm{N}_{11}\right)$. Thus, under $\mathrm{H}_{0}$, the likelihood (16) becomes

$$
\begin{equation*}
L\left(p^{*}\right)=\left(1-p^{*}\right)^{N_{00}}\left(p^{*}\right)^{N_{01}}\left(1-p^{*}\right)^{N_{10}}\left(p^{*}\right)^{N_{11}}=L\left(p^{*}\right)=\left(1-p^{*}\right)^{T-N_{1}}\left(p^{*}\right)^{N_{1}} \tag{17}
\end{equation*}
$$

Note that $N_{00}+N_{10}=T-N_{1}$ and $N_{01}+N_{11}=N_{1}$. Finally, the $L R_{\text {ind }}$ statistic is

$$
\begin{equation*}
\mathrm{LR}_{\mathrm{ind}}=-2 \log \left[\frac{\mathrm{~L}\left(\mathrm{p}^{*}\right)}{\mathrm{L}(\hat{\Pi})}\right] \sim \chi_{\mathrm{df}=1}^{2} \tag{18}
\end{equation*}
$$

### 4.2.3. Conditional coverage tests

The goal is to evaluate the adequacy of coverage, conditional on the independence of $\mathrm{p}-\mathrm{VaR}$ violations. The first backtest is the Christoffersen (1998) cc. Its hull hypothesis is $\mathrm{H}_{0}: \pi_{01}=\pi_{11}=\mathrm{p}$. Thus, its statistic can be derived directly from (18), where p replaces $\mathrm{p}^{*}$ :

$$
\begin{equation*}
\mathrm{LR}_{\mathrm{cc}}=-2 \log \left[\frac{\mathrm{~L}(\mathrm{p})}{\mathrm{L}(\hat{\Pi})}\right] \sim \chi_{\mathrm{df}=2}^{2} \tag{19}
\end{equation*}
$$

Moreover, $\mathrm{L}\left(\mathrm{p}^{*}\right)$ in (17) is exactly the denominator of the $\mathrm{LR}_{\text {ис }}$ statistic. This implies that $\mathrm{LR}_{\mathrm{cc}}=\mathrm{LR}_{\mathrm{uc}}+\mathrm{LR}_{\mathrm{ind}}$. Under $\mathrm{H}_{0}, \mathrm{LR}_{\mathrm{cc}}$ follows a $\chi^{2}$ with 2 degrees of freedom.

The second backtest is the DQ of Engle and Manganelli (2004). The null hypothesis can be rewritten as $H_{0}: E_{t-1}\left[h_{t}\right]=0$, where $h_{t}=I_{t}-p$. Hence, $H_{0}$ can be tested with the following linear regression model:

$$
\mathrm{h}_{\mathrm{t}}=\alpha_{0}+\alpha_{1} \mathrm{~h}_{\mathrm{t}-1}+\ldots+\alpha_{\mathrm{n}} \mathrm{~h}_{\mathrm{t}-\mathrm{n}}+\beta_{1} \operatorname{VaR}_{\mathrm{t}-1}^{\mathrm{p}}+\beta_{2} \operatorname{VaR}_{\mathrm{t}-2}^{\mathrm{p}}+\ldots+\beta_{\mathrm{n}} \operatorname{VaR}_{\mathrm{t}-\mathrm{n}}^{\mathrm{p}}+\mathrm{u}_{\mathrm{t}}
$$

where all the coefficients, $\alpha_{0}, \alpha_{k}, \beta_{k}, \mathrm{k}=1, \ldots, \mathrm{n}$, must be simultaneously nil. This can be done using Wald test, whose statistic follows a $\chi^{2}$ with $2 \mathrm{n}+1$ degrees of freedom.

## CVaR testing

### 4.2.4. $\mathrm{Z}_{\mathrm{ES}}$ test of Acerbi and Szekely (2019)

The backtest of Acerbi and Szekely (2019) exists in two versions: absolute or relative. We will consider the absolute version, whose statistic is

$$
\begin{equation*}
\mathrm{Z}_{\mathrm{ES}}\left(\mathrm{Y}_{\mathrm{t}}\right)=\frac{1}{\mathrm{~T}} \sum_{\mathrm{t}=1}^{\mathrm{T}}\left[\mathrm{CVaR}_{\mathrm{p}, \mathrm{t}}-\mathrm{VaR}_{\mathrm{p}, \mathrm{t}}+\left(\mathrm{Y}_{\mathrm{t}}+\operatorname{VaR}_{\mathrm{p}, \mathrm{t}}\right) \frac{\mathrm{Y}_{\mathrm{t}}<-\mathrm{VaR}_{\mathrm{p}, \mathrm{t}}}{\mathrm{p}}\right] \tag{20}
\end{equation*}
$$

The null hypothesis is $\mathrm{H}_{0}: \mathrm{E}\left[\mathrm{Z}_{\mathrm{ES}}\left(\mathrm{Y}_{\mathrm{t}}\right)\right]=0$ against $\mathrm{H}_{1}: \mathrm{E}\left[\mathrm{Z}_{\mathrm{ES}}\left(\mathrm{Y}_{\mathrm{t}}\right)\right] \neq 0$. To evaluate $\mathrm{H}_{0}$, we draw $N$ random vectors, $\left\{X_{t}^{j}\right\}_{\mathrm{t}=1, \ldots, \mathrm{~T}}^{\mathrm{j}=1, \ldots, \mathrm{~N}}$ depending on model parameters relating to each day $t$. Applying (20) to $\left\{X_{t}^{j}\right\}$ vectors generates the series $\left\{Z_{E S}\left(X_{t}^{j}\right)\right\}^{j=1, \ldots, N}$. The two-sided $p$-value is then determined by

$$
2 \times \min \left\{\mathrm{P}\left(\mathrm{Z}_{\mathrm{ES}}\left(\mathrm{X}_{\mathrm{t}}^{\mathrm{j}}\right)<\mathrm{Z}_{\mathrm{ES}}\left(\mathrm{Y}_{\mathrm{t}}\right)\right), \mathrm{P}\left(\mathrm{Z}_{\mathrm{ES}}\left(\mathrm{X}_{\mathrm{t}}^{\mathrm{j}}\right)>\mathrm{Z}_{\mathrm{ES}}\left(\mathrm{Y}_{\mathrm{t}}\right)\right)\right\} .
$$

### 4.2.5. RC test of Righi and Ceretta (2015)

The second backtest, denoted RC, is proposed in Righi and Ceretta (2015). Its statistic is defined by the expression

$$
\begin{equation*}
\operatorname{RC}\left(\mathrm{Y}_{\mathrm{t}}\right)=\frac{1}{\mathrm{~T}} \sum_{\mathrm{t}=1}^{\mathrm{T}} \frac{\left(\mathrm{Y}_{\mathrm{t}}-\mathrm{CVaR}_{\mathrm{p}, \mathrm{t}}\right) \times\left(\mathrm{Y}_{\mathrm{t}}<-\mathrm{VaR}_{\mathrm{p}, \mathrm{t}}\right)}{\mathrm{SD}_{\mathrm{p}, \mathrm{t}}}, \tag{21}
\end{equation*}
$$

where $\mathrm{SD}_{\mathrm{p}, \mathrm{t}}=\sqrt{\text { variance }\left[\mathrm{Y}_{\mathrm{t}} \times\left(\mathrm{Y}_{\mathrm{t}}<-\mathrm{VaR}_{\mathrm{p}, \mathrm{t}}\right)\right]}$. The test $p$-value is obtained by a construction similar to $\mathrm{Z}_{\mathrm{ES}}$.

### 4.3. Comparative backtesting

The comparative backtesting is based on scoring functions. A scoring function assigns an asymmetric penalty depending on the deviation between the realized return and its corresponding ex-ante risk coverage. Being a penalty, it is thus meant to be minimized.

### 4.3.1. Scoring functions for VaR

Let $y_{t}$ be the realized return and $v_{t}$ the p-VaR of day $t$. Gneiting and Raftery (2007, eq. (40)) show a general form of strictly consistent scoring functions for VaR:

$$
\begin{equation*}
S_{v}\left(v_{t}\right)=\left(I_{t}-p\right) \times G\left(-v_{t}\right)-I_{t} \times G\left(y_{t}\right)+\eta\left(y_{t}\right), \tag{22}
\end{equation*}
$$

where $I_{t}=1\left(y_{t}<-v_{t}\right)$, and $G$ and $\eta$ are functions. $\eta$ must be integrable, and $G$ continuously differentiable and strictly increasing. We then have

$$
\operatorname{VaR}_{\mathrm{t}}^{\mathrm{p}}=\arg \min _{\mathrm{v}_{\mathrm{t}}} \mathrm{E}_{\mathrm{t}-1}\left[\mathrm{~S}_{\mathrm{v}}\left(\mathrm{v}_{\mathrm{t}}\right)\right] .
$$

The value $S_{v}\left(v_{t}\right)$ is the score of day $t$. The expectation $E\left[S_{v}\left(v_{t}\right)\right]$ is the model score. We fix $\eta(x)=0$ and $G(x)=-\log (-x)$. $G$ is defined provided that VaR values $>0$. Having thus obtained the scoring function, $\mathrm{S}_{\log }$ has the expression

$$
\begin{equation*}
S_{\log }\left(v_{t}\right)=-\left(I_{t}-p\right) \log \left(v_{t}\right)+I_{t} \times \log \left(-y_{t}\right) \tag{23}
\end{equation*}
$$

This choice is motivated in NZ (2017, eq.(2.20)). Indeed, $\mathrm{S}_{\mathrm{log}}$ allows loss differences between competing forecasts to be 0 -homogenous (homogeneous of degree 0 ). This property is essential to have optimal power of the DM test (Diebold and Mariano, 1995).

### 4.3.2. Scoring functions for CVaR

Let $y_{t}, v_{t}$, and $e_{t}$ be, respectively, the realized return, the values of $p-V a R$ and $p-C V a R$ for day $t$. Fissler et al. (2016) propose a general form of strictly consistent scoring functions for CVaR:

$$
\begin{align*}
S_{v, e}\left(v_{t}, e_{t}\right) & =\left(I_{t}-p\right)\left(G_{1}\left(-v_{t}\right)-G_{1}\left(y_{t}\right)\right)-\frac{1}{p} G_{2}\left(-e_{t}\right) I_{t}\left(v_{t}+y_{t}\right)  \tag{24}\\
& +G_{2}\left(-e_{t}\right)\left(-e_{t}+v_{t}\right)-g_{2}\left(-e_{t}\right)+\eta\left(y_{t}\right)
\end{align*}
$$

where $I_{t}=1\left(y_{t}<-v_{t}\right), \eta$ is integrable, $G_{1}$ is an increasing function ${ }^{4}$ twice continuously differentiable and integrable once. $G_{2}$ is the derivative of $g_{2}\left(g_{2}^{\prime}=G_{2}\right)$, with $g_{2}$ strictly increasing and strictly concave. We then have, for optimal VaR/CVaR :

$$
\left(\operatorname{VaR}_{t}^{p}, \operatorname{CVaR}_{t}^{p}\right)=\arg \min _{\left(v_{t}, e_{t}\right)} E_{t-1}\left[S_{v, e}\left(v_{t}, e_{t}\right)\right] .
$$

[^4]We choose $G_{1}(x)=0, G_{2}(x)=-1 / x$ and $\eta(x)=0$. Therefore, $g_{2}(x)=-\log (-x)$. The scoring function thus obtained, $\mathrm{S}_{\mathrm{FZ}}$, is

$$
\begin{equation*}
S_{F Z}\left(v_{t}, e_{t}\right)=\frac{1}{e_{t}}\left(v_{t}-\frac{I_{t}}{p}\left(y_{t}+v_{t}\right)\right)+\log \left(e_{t}\right)-1 . \tag{25}
\end{equation*}
$$

$\mathrm{S}_{\mathrm{FZ}}$ is chosen because it allows loss differences between competing forecasts to be 0homogeneous ( NZ, 2017, eq.(2.24), and Patton et al., 2019, eq.(6)).

The variable $\mathrm{v}_{\mathrm{t}}$ is present in (25) and (24), and can't be eliminated. More generally, Gneiting (2011) shows that there is no strictly consistent scoring function where $e_{t}$ appears alone without $v_{t}$. This is why CVaR is not elicitable by itself, but the pair VaR/CVaR is.

### 4.3.3. DES test (goodness-of-fit test of Patton et al., 2019)

From equation (25) defining $\mathrm{S}_{\mathrm{FZ}}$, Patton et al. (2019) show that, under the assumption of a correct model specification for VaR and CVaR , the first-order conditions $\partial \mathrm{E}_{\mathrm{t}-1}\left[\mathrm{~S}_{\mathrm{FZ}}\left(\mathrm{v}_{\mathrm{t}}, \mathrm{e}_{\mathrm{t}}\right)\right] / \partial \mathrm{v}_{\mathrm{t}}=0$ and $\partial \mathrm{E}_{\mathrm{t}-1}\left[\mathrm{~S}_{\mathrm{FZ}}\left(\mathrm{v}_{\mathrm{t}}, \mathrm{e}_{\mathrm{t}}\right)\right] / \partial \mathrm{e}_{\mathrm{t}}=0$ imply that the variables $\lambda_{\mathrm{v}}^{\mathrm{s}}=\mathrm{I}_{\mathrm{t}}-\mathrm{p}$ and $\lambda_{\mathrm{e}}^{s}=\mathrm{I}_{\mathrm{t}} \mathrm{y}_{\mathrm{t}} /\left(\mathrm{pe}_{\mathrm{t}}\right)-1$ are conditionally mean zero, such that

$$
\begin{gather*}
E_{t-1}\left[\lambda_{\mathrm{v}, \mathrm{t}}^{\mathrm{s}}\right]=\mathrm{E}_{\mathrm{t}-1}\left[\mathrm{I}_{\mathrm{t}}\right]-\mathrm{p}=0  \tag{26}\\
\mathrm{E}_{\mathrm{t}-1}\left[\lambda_{\mathrm{e}, \mathrm{t}}^{\mathrm{s}}\right]=\mathrm{E}_{\mathrm{t}-1}\left[\frac{\mathrm{I}_{\mathrm{t}} \mathrm{y}_{\mathrm{t}}}{\mathrm{p} \times \mathrm{e}_{\mathrm{t}}}-1\right]=0 . \tag{27}
\end{gather*}
$$

Equality (26) is, interestingly, the same as the DQ null hypothesis. So, to test (27), Patton et al. (2019) employ the same technique as Engle and Manganelli (2004) and rely on the linear regression:

$$
\begin{equation*}
\lambda_{\mathrm{e}, \mathrm{t}}^{\mathrm{s}}=\mathrm{b}_{0}+\mathrm{b}_{1} \lambda_{\mathrm{e}, \mathrm{t}-1}^{\mathrm{s}}+\mathrm{b}_{2} \mathrm{e}_{\mathrm{t}}+\mathrm{u}_{\mathrm{t}} \tag{28}
\end{equation*}
$$

where $u_{t}$ is an error term, and $\left(b_{0}, b_{1}, b_{2}\right)$ are the regression coefficients, which must be simultaneously zero under the null hypothesis (against the two-sided alternative). Compared to the Patton et al. (2019) approach, these authors state on page 406 that "similar conditional calibration tests are presented in Nolde and Ziegel (2017)."

Based on the aforementioned facts, we now know that DQ does more than evaluate conditional coverage: it also assesses the models' ability to produce an optimal VaR while minimizing $\mathrm{S}_{\mathrm{log}}$. Using the preceding arguments, and the parallel analogy between VaR and CVaR, we assert that the CVaR part of the Patton et al. (2019) construction (equations 27 and 28) is valid for testing the CVaR conditional adequacy. We refer to it as the DES test henceforth. This illustrates the key advantages of exploiting the close relationship between traditional and comparative backtesting techniques and employing them concurrently.

### 4.3.4. DM test of Diebold and Mariano (1995)

The purpose of the test is to compare forecasts between two models, $M_{i}$ and $M_{j}$, using an appropriate scoring function, $S$. We construct the loss-difference vector $d_{i j}=\left\{S\left(M_{i}\right)-S\left(M_{j}\right)\right\}_{t=1}^{T}$. The null hypothesis is $H_{0}: E\left[S\left(M_{i}\right)-S\left(M_{j}\right)\right]=0$. The DM statistic is the mean of $d_{i j}$, normalized by its standard deviation, estimated with a heteroskedasticity and autocorrelation consistent (HAC) correction. We apply the Harvey et al. (1997) correction with a lag $=5$ to account for the strong autocorrelation persistence. Under $\mathrm{H}_{0}$, the DM statistic follows a Student$t$ of $\mathrm{T}-1$ degrees of freedom.

### 4.4. Approach to conducting backtesting

Let us recall that our primary goal is to orchestrate all the procedures and actions to specifically meet the Basel regulations' requirements (BCBS, 2016, p.77; BCBS, 2019, §32.5). We must also fulfill the Basel recommendation to foresee additional complementary procedures and statistical tests, with varying degrees of confidence, to support the model's accuracy and robustness (BCBS, 2016, p.82; BCBS, 2019, §32.13).

The components involved are as follows: 6 backtests (uc, cc, $\mathrm{DQ}, \mathrm{Z}_{\mathrm{ES}}, \mathrm{RC}, \mathrm{DES}$ ), 3 p levels $(1 \%, 2.5 \%, 5 \%)$, and 2 scoring functions ( $\mathrm{S}_{\mathrm{log}}$ and $\mathrm{S}_{\mathrm{FZ}}$ ), for a total of 22 competing models. The calculations yield $22 \times 6$ backtests $\times 3$ p-levels $=396$ backtests to investigate, and $22 \times 2 \times 3=132$ scores to analyze pairwise using $2 \times 3=6 \mathrm{DM}$ test matrices. These are symmetrical non-diagonal matrices, each of which has $22 \times(22-1) / 2=231$ pairs of
statistics $/ p$-values. Therefore, $6 \times 231=1386$ DM statistics should be examined for signs and significance. To summarize, $396+1386=1782$ different statistical tests would have to be conducted and reviewed!

We are obviously not going to do that. To achieve the backtesting process much more efficiently, we propose the following collaborative approach. The study begins with $\mathrm{p}=1 \%$, which corresponds to Basel's explicit requirement of backtesting on VaR. The guiding idea is to select from the top-10 competing models on the basis of their ranking by $\mathrm{S}_{\mathrm{log}}$. Each selected model first undergoes an evaluation via the six backtests. The forecasts of successful models are then compared in pairs by DM matrices.

The resulting subset of models undergoes a similar circuit for $\mathrm{p}=2.5 \%$, the regulatory coverage by CVaR level. Finally, the remaining models are assessed for $p=5 \%$, as an additional complement. The number of models thus diminishes progressively. Therefore, scoring functions concentrate on worthwhile models, whereas conventional backtests perform the final individual validation along with the DM test.

## 5. Backtesting results

We begin by focusing on $1 \%$-VaR backtest. For this purpose, our criteria (1a) demand that all three VaR tests, uc, cc, and DQ , be carried out with no rejection at the $10 \%$-threshold. We also concentrate on CVaR, as per Basel recommendations, for additional tests. We deploy three tests: $\mathrm{Z}_{\mathrm{ES}}, \mathrm{RC}$, and the DES test. To meet criteria (1b), at least two of the three tests must not reject the model at the $5 \%$-threshold. The supplement (1b) ensures that enough tail thickness is captured.

Table 5 displays the results. Columns (1) to (4) show the three VaR tests; columns (5) and (6), the $\mathrm{Z}_{\mathrm{ES}}$ and RC standard tests; column (11) presents DES results on the conditional adequacy of CVaR. Scores and ranks of $\mathrm{S}_{\mathrm{log}}$ are in columns (7) and (8). Columns (9) and (10) contain the corresponding elements for $\mathrm{S}_{\mathrm{FZ}}$. Rankings are based on the entire 22 models, including both prefilterings.

For $\mathrm{p}=1 \%$, Panel A presents the 12 highest-rated models using $\mathrm{S}_{\mathrm{log}}$. Two of them, however, are problematic. The first is e|1:T, which, despite ranking fourth out of 22, is nonetheless strongly rejected by uc, contradicting the VaR scoring ranking. Furthermore, cc and DQ reject this model (respective $p$-values as low as $0.005,0.012$, and 0.001 ). Additionally, all CVaR tests reject e| $1: \mathrm{T}$ with $p$-values of $0.001,0.006$, and 0.015 .

This example shows that a favorable ranking by a consistent scoring function does not prevent adverse results in conventional backtests. On the other hand, it is interesting to note that six models from Panel A have the exact same number of violations of $1 \%-\mathrm{VaR}, 17$, and therefore, identical uc results. So, while uc results alone cannot be used to differentiate among them, the VaR scoring function can. This combination of observations highlights not only the complementarity of conventional and comparative backtesting components, but also the need to integrate the capabilities they each offer.

We have a second case of rejection. Model e|1:ST3, 7th out of 22, fails uc as well as DQ, $\mathrm{Z}_{\mathrm{ES}}$, and RC (respective $p$-values of $0.061,0.054<10 \% ; 0.001$ and $0.026<5 \%$ ). In fact, e|1:ST3 is expected to deliver average to poor results, since it has an ST3 density arbitrarily imposed on both stages. Meanwhile, being ranked 7th, e|1:ST3 is therefore believed to be equivalent to or better than almost three-quarters of the 22 models. This provides a first indication of how inefficient the n-prefiltering stage might be. At the same time, it also shows how difficult it is to model the $1 \%$ level properly.

The point to note now is that $\mathrm{n} \mid 2$ SEP3 is the only model resulting from Gaussian prefiltering. This shows, yet again, how weak this n-prefiltering is. Interestingly, despite the problematic n-prefiltering, the $\mathrm{n} \mid 2: \mathrm{SEP} 3$ model ranked 5th and 3rd overall for VaR and CVaR, respectively (columns (8) and (11)), revealing one aspect of the superiority of the $2: \mathrm{SEP} 3$ mixture.

Let us now highlight that e|2:SEP3 takes first place in Panel A and passes all six tests with very comfortable $p$-values. In addition to e|2:SEP3, $\mathrm{n} \mid 2: S E P 3$ is the only model in Panel A that meets criteria (1a) and surpasses (1b), since it passes all CVaR tests. The last four models of Panel A are removed for failing two or more CVaR tests. We are left with six potential models: e|2:SEP3, $\mathrm{e}|1: \mathrm{EGB} 2, \mathrm{e}| 1: \mathrm{SEP} 3, \mathrm{n}|2: \mathrm{SEP} 3, \mathrm{e}| 1: \mathrm{GP}$, and e|2:SN2. We need the DM test to discern their loss
differences. The e|2:SEP3 score of $\mathbf{- 3 . 2 7 0 7}$ clearly stands out from the others, which are all rather close to each other.

The DM statistics of Table 6 are calculated by subtracting the forecasts of the row models from those of the column models. Thus, a negative statistic favors the line model, and vice versa. The improvement is confirmed when the statistic is significant at $5 \%$. The e|2:SEP3 model shows all negative and significant statistics at $5 \%$ or better. The predictive power of this model is much higher than the others. The remaining five models, according to DM test, cannot be discriminated at $5 \%$. That said, keep in mind that $\mathrm{n} \mid 2$ SEP3 has an indisputable advantage over the other four models in meeting criteria (1a) and exceeding (1b).

Panel B of Table 5 displays the six models selected from Panel A, now sorted according to $\mathrm{S}_{\mathrm{FZ}}$ scores (column (9)). Recall that this is the level of regulatory coverage calculation with $2.5 \%-$ CVaR. So, the CVaR criteria should be tighter. Criteria (2a) require no rejection by any of $Z_{\mathrm{ES}}$, RC, or DES at the $10 \%$-threshold. Criteria (2b) for VaR also require no rejection by any of the three VaR tests at $10 \%$, which can be quite stringent due to the joint elicitability of VaR and CVaR. A proper VaR assessment is essential for a successful CVaR validation.

Once again, e|2:SEP3 takes first place. This model easily passes all conditions (2a) and (2b) with comfortable $p$-values. Model e|2:SN2 also succeeds in all criteria, with decent $p$-values (see also the SN2's performance in Dionne and Saissi Hassani, 2017). Note that e|1:GP is ranked third, but fails ( 2 a ) criteria ( $\mathrm{RC} p$-value $=0.089<10 \%$ ). Yet again, an excellent scoring does not always imply success in backtests. The next model to consider is n|2:SEP3, which is ranked 4th and almost as easily meets (2a) and (2b) criteria as e|2:SEP3.

Notice how close the $\mathrm{S}_{\mathrm{Fz}}$ scores for e|2:SN2 and e|1:GP are. Given the excellent performance of the first and the rejection of the latter, there is inconsistency. We want to see if the DM test can detect it. We also need confirmation that $\mathrm{n} \mid 2$ :SEP3 can be considered the third choice in Panel 2.5\% (after removing e| 1 GP ).

The pairwise DM test matrix of the six Panel B models is shown in Table 7. There are two key facts to point out. The first is that there is not enough evidence to identify the defaulter, e|1:GP, from the others: e|2:SEP3, e|2:SN2, and n|2:SEP3. In fact, e|1:GP would even have been considered
satisfactory as Panel B's third choice if we hadn't done the backtests. The complementary nature of backtesting tools proves quite useful once again. The second point is that, despite small advantages between models $\mathrm{e}|2: \mathrm{SEP} 3, \mathrm{e}| 2: \mathrm{SN} 2$, and $\mathrm{n} \mid 2: \mathrm{SEP} 3$, there is no evidence to differentiate them (DM statistics are negative but not significant). As a result, the three models that emerge through the criteria of Panels A and B are e|2:SEP3, $\mathrm{n} \mid 2: \mathrm{SEP} 3$, and $\mathrm{e} \mid 2: \mathrm{SN} 2$.

On the other hand, e $\mid$ : EGB 2 and e $\mid 1: S E P 3$ are rejected by both RC and DES. Incidentally, the single-density models, e|1:EGB2, e|1:SEP3, and e|1:GP, appear to behave similarly at the $2.5 \%$ and $1 \%$ levels, all passed $\mathrm{p}=1 \%$ decently, but are now rejected for the $2.5 \%$ level.

In Panel C of Table 5, we assess our three models' adequacy for the traditional $\mathrm{p}=5 \%$ level. The criteria we set here are the same as before, namely, (3a), no rejection by any CVaR tests at $10 \%$, and (3b), no rejection by any VaR tests at $10 \%$, either. Everything is fine for e|2:SEP3 and $\mathrm{e} \mid 2: S N 2$. However, $\mathrm{n} \mid 2:$ SEP3 does show a weakness on both VaR and CVaR $(\mathrm{DQ} p$-value $=0.023$; DES $p$-value $=0.060$ ). This could be due to residual autocorrelations or volatility clustering left by the n-prefilter. Despite this, given its strong performance at the regulatory and extremely difficult levels, we do not believe this to be a problem for $\mathrm{n} \mid 2:$ SEP3 .

Finally, to provide a further analysis of individual model evaluations not discussed here, Tables A. 4 and A. 5 contain complete information about all backtesting outcomes for n-prefiltering and e-prefiltering, respectively. For instance, we can see in Table A.4, regarding n-prefiltered models, a significant decline in the CVaR sufficiency, as evidenced by the three CVaR tests, compared to e-prefiltered models in Table A.5. In addition, DQ and DES reveal serious difficulties for n-prefiltered models to deal with residual autocorrelations and volatility clustering that the Gaussian prefilter fails to account for.

## Discussion and conclusion

We can draw some conclusions from our examination of the facts outlined above. First and foremost, the superiority of the SEP3 mixture has been demonstrated for our extremely difficult data in VaR and CVaR conditional forecasting at the regulatory levels of $1 \%$ and $2.5 \%$, as well as the complementary $5 \%$ level. With an effective Skew- $t$ prefilter, e|2:SEP3 behaved strongly. It is
far more interesting, however, to learn that $\mathrm{n} \mid 2: \mathrm{SEP} 3$ even overcame the poor Gaussian prefiltering, whereas no other n-prefiltered model even appeared in the top-10 regulatory $1 \%$ panel. The lower efficacy of the single-density e|1:SEP3, as compared to e|2:SEP3, again illustrated the strength of the 2:SEP3 mixture in conditional modeling. Our findings support and expand those of Haas (2009), Broda and Paolella (2011), Miao et al. (2016), Rombouts and Bouaddi (2009), Zhu and Galbraith (2011), and Kim and Lee (2021).

When we compare GP to the 2 :SEP3 mixture, we see that, unlike $\mathrm{n} \mid 2: \mathrm{SEP} 3$, the Gaussian prefiltered $\mathrm{n} \mid 1$ :GP ranked rather near the end: 15 th in the $1 \%$ panel (see Table A.4). On the other hand, the e-prefiltered e|1:GP was not well ranked in Panel A (6th), well behind e|2:SEP3 (1st) as well as behind $n \mid 2$ SEP3 (5th). Furthermore, in the $2.5 \%$ panel, even e|1:GP was rejected. Finally, GP had no chance against the 2:SEP3 mixture.

A possible shortcoming of this work is that we could also have done the calculations according to a third prefilter built on Student-t. The results would have been more complete, but this would have overloaded the paper. Also, a second point we wanted to look into was which models could fill in the substantial gaps left by poor Gaussian prefiltering. n|2:SEP3 was the only one.

Two-density mixtures (made up of two densities) appear to be an optimal combination. They can improve risk modeling by more precisely capturing the properties of the relevant tail for downside risk. Each density can represent the tail fatness and skewness of each side of the data distribution separately. To approach this fact differently, despite being Skew- $t$ prefiltered, no single-density models were retained in the final selection, including the well-known GP and EGB2-not even the single-SEP3.

Many indications in Section 3 are also revealed in Section 5 findings. Here, we emphasize the importance of comparing sample empirical estimates to model-derived measures, to quickly assess model traits. This guides the research strategy and the direction in which to proceed. Interestingly, analyzing model-derived CVaR within, or not too far from the $[\mathrm{CVaR}-, \mathrm{CVaR}+$ ] range, provides quick information that correlates with backtesting conclusions. We think the concept should be further explored in future research.

The next point to consider is how crucial it is to model both the prefiltering and fitting stages properly. While the inefficiency of n-prefiltering is obvious, e-prefiltering might still have left some residual thickness and skewness unaccounted for. Interestingly, we can see this in the severe rejection of e|3:NO and e|2:NO by two CVaR tests, while models like e|1:GP were able to capture residual tail thickness. The presence of residual skewness in e-prefiltering can be proved, since $\mathrm{e} \mid 2: \mathrm{SN} 2$ managed to capture it using its two supplementary parameters, whereas neither e|2:NO nor $\mathrm{e} \mid 3: \mathrm{NO}$ could. As a result, even a successful prefiltering, such as the one built with Skew- $t$, could still be incomplete by itself. The quality of the fitting stage is unquestionably equally critical.

We used what we called a collaborative approach to enhance model-evaluation efficiency, using mixed backtesting tools. The effort can concentrate on relevant and worthwhile competitors pinpointed among numerous models by appropriate scoring functions. On the other hand, a prominent example to illustrate the need to combine the two branches of backtesting is e|1:T, which was severely rejected by all standard backtests for $\mathrm{p}=1 \%$, while it was rather well rated by $\mathrm{S}_{\mathrm{log}}$. This was also the case, albeit less intensely, for e| 1 :ST3 at $1 \%$ and e $\mid 1: \mathrm{GP}$ at the $2.5 \%$ level.

Regarding the abovementioned issue of models being rejected by backtests despite having excellent scoring, the exact opposite situation was stated in NZ(2017). Indeed, their study revealed models that rated poorly but that were not rejected by traditional backtesting, while they should have been (data simulated with misspecification). They advise checking models that pass traditional backtests alongside an appropriate scoring function. We support this proposition while also advocating for the opposite outcome. Excellent scoring alone, or passing conventional backtests alone, should no longer be considered enough to approve a model.

By analogy with DQ, we employed DES to backtest the conditional adequacy of CVaR, whereas its original purpose was to assess model forecasting optimality. The mechanism is straightforward to document. Low-rated models would not minimize the scoring function. Firstorder conditions cannot be met. Thus, DQ or DES (or equivalent conditional tests) should disqualify them. This further illustrates how interesting it can be to take advantage of the close relationship between both backtesting branches. Backtesting can thus achieve significant theoretical and practical advancements.

In addition to fully supporting the concurrent use of all backtesting approaches, we believe that regulators will soon consider incorporating the best of them into a future standardized "minimum backtesting requirement" procedure.

# Forecasting VaR and CVaR based on Skewed Exponential Power mixture in compliance with the new market risk regulation 

7 July 2022

## Online Appendices

The appendices present mathematical developments of VaR and CVaR formulas of competing models. Table A. 1 shows the symbols of different models. Appendix A2 presents the general expression of CVaR. Appendix A3 shows how to compute CVaR for a mixture of distributions. Appendixes A4 to A10 develop the CVaR formulas for different statistical distributions. Appendix A11 derives an optimal portfolio, which serves as input data beginning in Section 3. Complementary tables are presented in Appendix A12.

## A1. Estimated models

Table A. 1
Model symbol definitions

| Model | Symbol | Description of the model |
| :--- | :--- | :--- |
| M1 | $1:$ NO | Normal distribution |
| M2 | $1:$ T | Student- $t$ distribution |
| M3 | $1:$ EGB2 | Exponential GB2 distribution |
| M4 | $2:$ NO | Mixture of 2 normal distributions |
| M5 | $2: \mathrm{T}$ | Mixture of 2 Student- $t$ distributions |
| M6 | 3:NO | Mixture of 3 normal distributions |
| M7 | 2:SN2 | Mixture of 2 SN2 distributions |
| M8 | 2:SEP3 | Mixture of 2 SEP3 distributions |
| M9 | 1:ST3 | Skew- $t$ distribution (type 3) |
| M10 | 1:SEP3 | SEP3 distribution |
| M11 | 1:GP | Generalized Pareto distribution |

## A2. General expression of CVaR

We are interested in the family of location-scale parametric distributions $\overline{\mathrm{F}}$. For a distribution $\mathrm{F} \in \overline{\mathrm{F}}$ and a r.v. $\mathrm{Y} \sim \mathrm{F}$, the reduced variable $\mathrm{Z}=(\mathrm{Y}-\mu) / \sigma$, where $\mu$ and $\sigma$ denote location and scale parameters, follows the distribution $\mathrm{F}^{0}$ defined by:

$$
\mathrm{F}(\mathrm{y})=\mathrm{F}^{0}(\mathrm{z})
$$

where $y$ and $z$ are generic variables for $Y$ and $Z$ random variables, respectively.
$F^{0}$ is the reduced cumulative function of $F$. The reduced density $f^{0}(\cdot)$ is related to the density $f(\cdot)$ by:

$$
\begin{equation*}
f(y)=\frac{f^{0}(z)}{\sigma} \tag{A0}
\end{equation*}
$$

In the following, downside risk is located in the left tail (negative returns). The risk measures are taken in absolute value, so they are positive. The probability level p corresponds to the degree of confidence $(1-\mathrm{p})$. The p -quantile $\mathrm{q}=$ Quantile $(\mathrm{Y}$, level $=\mathrm{p})$, so $\mathrm{q}<0$ (left tail). In the other hand, we note $\mathrm{e}=\mathrm{E}[\mathrm{Y} \mid \mathrm{Y} \leq \mathrm{q}]$, which means $\mathrm{e}<0$ (left tail). Then we compute $\mathrm{p}-\mathrm{VaR}=-\mathrm{q}$ and $\mathrm{p}-\mathrm{CVaR}=-\mathrm{e}$.

According to Broda and Paolella (2011), the tail quantity of a density $\mathrm{f}(\cdot)$ at point $x$ is defined by: $\operatorname{tail}_{f}(x) \stackrel{\text { def }}{=} \int_{-\infty}^{x} t f(t) d t$. We develop the expression of CVaR using this definition:

$$
\begin{align*}
e & =E[Y \mid Y \leq q]=\frac{1}{F(q)} \int_{-\infty}^{q} y f(y) d y  \tag{A1}\\
& =\frac{1}{p}\left\{\int_{-\infty}^{\frac{q-\mu}{\sigma}}(\mu+\sigma z) \frac{f^{0}(z)}{\sigma} \sigma d(z)\right\}  \tag{A2}\\
& =\frac{1}{p}\left\{\int_{-\infty}^{\frac{q-\mu}{\sigma}} \mu f^{0}(z) d z+\sigma \int_{-\infty}^{\frac{q-\mu}{\sigma}} z f^{0}(z) d(z)\right\}  \tag{A3}\\
& =\frac{1}{p}\left\{\mu F^{0}\left(\frac{q-\mu}{\sigma}\right)+\sigma \operatorname{Tail}_{f^{0}}\left(\frac{q-\mu}{\sigma}\right)\right\} \tag{A4a}
\end{align*}
$$

Equation (A2) is obtained by using (A0) after a change of variable $z=(y-\mu) / \sigma$, or $y=\mu+\sigma z, s o, d y=\sigma d z$. Note that there are two parts in formula (A4a): the first one is $\mu / p$ times the centered reduced cumulative $\mathrm{F}^{0}(\cdot)$ evaluated at the centered reduced quantity $(q-\mu) / \sigma$. The second one is $\sigma / p$ times the tail of $f^{0}$, also evaluated at $(q-\mu) / \sigma$. CVaR is finally:

$$
\begin{equation*}
\mathrm{CVaR}_{\mathrm{f}}=-\mathrm{e}=-\frac{1}{\mathrm{p}}\left\{\mu \mathrm{~F}^{0}\left(\frac{\mathrm{q}-\mu}{\sigma}\right)+\sigma \operatorname{Tail}_{\mathrm{f}^{0}}\left(\frac{\mathrm{q}-\mu}{\sigma}\right)\right\} \tag{A4}
\end{equation*}
$$

An important remark is that we have of $\operatorname{course} \mathrm{F}^{0}((\mathrm{q}-\mu) / \sigma)=\mathrm{p}$, which would simplify the expression (A4). Even so, we will leave the expression as it is so that it will be of the same form as for mixtures of distributions where there will be several cumulatives $\mathrm{F}_{\mathrm{i}}^{0}(\cdot)$, for which $\mathrm{F}_{\mathrm{i}}^{0}((\mathrm{q}-\mu) / \sigma) \neq \mathrm{p}$.

## A3. CVaR of a mixture of distributions

Let $m(\cdot)$ be a mixture of $n$ densities $f_{i}(\cdot), i=1, \ldots, n$. Each density $f_{i} \in \bar{F}$ has a parameter of location $\mu_{\mathrm{i}}$ and scale $\sigma_{\mathrm{i}}$. The mixture density $\mathrm{f}_{\mathrm{m}}(\cdot)$ and its distribution $\mathrm{F}_{\mathrm{m}}(\cdot)$ are written as:

$$
\mathrm{f}_{\mathrm{m}}(\mathrm{y})=\sum_{1}^{\mathrm{n}} \mathrm{c}_{\mathrm{i}} \mathrm{f}_{\mathrm{i}}(\mathrm{y}), \quad \mathrm{F}_{\mathrm{m}}(\mathrm{y})=\sum_{\mathrm{i}}^{\mathrm{n}} \mathrm{c}_{\mathrm{i}} \mathrm{~F}_{\mathrm{i}}(\mathrm{y})
$$

where $c_{i}$ is a probability, to be estimated, regarding the weight of density $f_{i}(\cdot)$. The sum of the $c_{i}$ is equal to 1 .

Let $q_{m}$ be the p-quantile of the mixture. We denote $f_{i}^{0}(\cdot)$ and $F_{i}^{0}(\cdot)$ as the reduced density and the reduced cumulative of the $i^{\text {th }}$ density. The calculations are such as:

$$
\begin{aligned}
& e=E\left[Y \mid Y \leq q_{m}\right]=\frac{1}{p} \int_{-\infty}^{q_{m}} y f_{m}(y) d y \\
& =\frac{1}{p} \sum_{1}^{n} c_{i} \int_{-\infty}^{q_{m}} y f_{i}(y) d(y) \\
& =\frac{1}{p} \sum_{1}^{n} c_{i} \int_{-\infty}^{\frac{q_{m}-\mu_{i}}{\sigma_{i}}}\left(\mu_{i}+\sigma_{i} z_{i}\right) \frac{f_{i}^{0}\left(z_{i}\right)}{\sigma_{i}} \sigma_{i} d\left(z_{i}\right) \\
& =\frac{1}{\mathrm{p}} \sum_{1}^{\mathrm{n}} \mathrm{c}_{\mathrm{i}}\left\{\mu_{\mathrm{i}} \mathrm{~F}_{\mathrm{i}}^{0}\left(\frac{\mathrm{q}_{\mathrm{m}}-\mu_{\mathrm{i}}}{\sigma_{\mathrm{i}}}\right)+\sigma_{\mathrm{i}} \operatorname{Tail}_{\mathrm{f}_{\mathrm{i}}^{0}}\left(\frac{\mathrm{q}_{\mathrm{m}}-\mu_{\mathrm{i}}}{\sigma_{\mathrm{i}}}\right)\right\}
\end{aligned}
$$

or, in vector form:

$$
\operatorname{CVaR}_{\mathrm{m}}=-\mathrm{e}=-\frac{1}{\mathrm{p}}\left(\begin{array}{c}
\mathrm{c}_{1} \\
\vdots \\
\mathrm{c}_{\mathrm{n}}
\end{array}\right)^{\mathrm{T}} \times\left(\left(\begin{array}{c}
\mu_{1} \\
\vdots \\
\mu_{\mathrm{n}}
\end{array}\right) \times\left(\begin{array}{c}
\mathrm{F}_{1}^{0}\left(\frac{\mathrm{q}_{\mathrm{m}}-\mu_{1}}{\sigma_{1}}\right) \\
\vdots \\
\mathrm{F}_{\mathrm{n}}^{0}\left(\frac{\mathrm{q}_{\mathrm{m}}-\mu_{\mathrm{n}}}{\sigma_{\mathrm{n}}}\right)
\end{array}\right)+\left(\begin{array}{c}
\sigma_{1} \\
\vdots \\
\sigma_{\mathrm{n}}
\end{array}\right) \times\left(\begin{array}{c}
\operatorname{Tail}_{\mathrm{f}_{1}}^{0}\left(\frac{\mathrm{q}_{\mathrm{m}}-\mu_{1}}{\sigma_{1}}\right) \\
\vdots \\
\operatorname{Tail}_{\mathrm{f}_{\mathrm{f}}}^{0}\left(\frac{\mathrm{q}_{\mathrm{m}}-\mu_{\mathrm{n}}}{\sigma_{\mathrm{n}}}\right)
\end{array}\right)\right] .
$$

Generally, $q_{m}$ is found numerically as a solution to the equation $F_{m}\left(q_{m}\right)-p=0$. Note that for a distribution $i, \mathrm{~F}_{\mathrm{i}}^{0}\left(\left(\mathrm{q}_{\mathrm{m}}-\mu_{\mathrm{i}}\right) / \sigma_{\mathrm{i}}\right) \neq \mathrm{p}$.

## A4. CVaR of a normal distribution

The density $\phi_{\mu, \sigma}(\cdot)$ of a normal distribution $N(\mu, \sigma)$ is:

$$
\phi_{\mu, \sigma}(\mathrm{y})=\frac{1}{\sigma \sqrt{2 \pi}} \exp \left(-\frac{1}{2}\left(\frac{\mathrm{y}-\mu}{\sigma}\right)^{2}\right)
$$

We denote both $\phi_{0}(\cdot)$ and $\Phi_{0}(\cdot)$ as the density and the cumulative of the standard normal distribution $\mathrm{N}(0,1)$. It is easy to show that:

$$
\begin{equation*}
\frac{\partial}{\partial \mathrm{x}} \phi_{0}(\mathrm{x})=-\mathrm{x} \phi_{0}(\mathrm{x}) \tag{A5a}
\end{equation*}
$$

For $\mathrm{Y} \sim \mathrm{N}(\mu, \sigma), \quad q$ being the p -quantile of Y is found by solving $\mathrm{P}(\mathrm{Y} \leq \mathrm{q})=\mathrm{P}\left(\mathrm{Z} \leq \frac{\mathrm{q}-\mu}{\sigma}\right)=\mathrm{p}$, hence:

$$
\mathrm{q}=\mu+\sigma \Phi_{0}^{-1}(\mathrm{p})
$$

Further, with the definition of tail and with the help of equation (A5a), we find:

$$
\begin{equation*}
\operatorname{Tail}_{\phi_{0}}(x)=\int_{-\infty}^{\mathrm{x}} \mathrm{z} \phi_{0}(\mathrm{z}) \mathrm{dz}=-\phi_{0}(\mathrm{x}) . \tag{A5}
\end{equation*}
$$

We apply (A4) and (A5) to obtain:

$$
\begin{equation*}
\mathrm{CVaR}_{\phi, \mu, \sigma}=-\frac{1}{\mathrm{p}}\left\{\mu \Phi_{0}\left(\frac{\mathrm{q}-\mu}{\sigma}\right)-\sigma \phi_{0}\left(\frac{\mathrm{q}-\mu}{\sigma}\right)\right\} . \tag{A6}
\end{equation*}
$$

## A5. CVaR of a Student- $\boldsymbol{t}$ distribution

The density $\mathrm{f}_{\mathrm{T}, \mu, \sigma, v}(\cdot)$ of the Student- $t$ of parameters $\mu$ (location), $\sigma$ (scale) and $\nu$ (degrees of freedom) is written as:

$$
\mathrm{f}_{\mathrm{T}, \mu, \sigma, v}(\mathrm{y})=\frac{\mathrm{A}}{\sigma}\left(1+\left(\frac{\mathrm{y}-\mu}{\sigma}\right)^{2} \frac{1}{v}\right)^{-\mathrm{b}}
$$

where $A=[\sqrt{v} \times B(1 / 2, v / 2)]^{-1}$ and $b=(v+1) / 2 . \quad B(\cdot)$ is the beta function. ${ }^{1}$ The reduced functions are noted $\mathrm{f}_{\mathrm{T}, \mathrm{v}}^{0}(\cdot)$ and $\mathrm{F}_{\mathrm{T}, \mathrm{v}}^{0}(\cdot)$. We determine $q$ from the $\operatorname{VaR}$ of $\mathrm{Y} \sim \mathrm{t}(\mu, \sigma, v)$ to the degree of confidence $(1-\mathrm{p})$ :

$$
\begin{aligned}
\mathrm{P}(\mathrm{Y} \leq \mathrm{q})=\mathrm{P}(\mu+\sigma \mathrm{Z} \leq \mathrm{q}) & \Rightarrow \mathrm{F}_{\mathrm{T}, v}^{0}\left(\frac{\mathrm{q}-\mu}{\sigma}\right)=\mathrm{p} \\
\mathrm{q} & =\mu+\sigma \mathrm{F}_{\mathrm{T}, v}^{0-1}(\mathrm{p})
\end{aligned}
$$

where $\mathrm{F}_{\mathrm{T}, v}^{0-1}(\cdot)$ is the quantile (or inverse) function of $\mathrm{F}_{\mathrm{T}, v}^{0}(\cdot)$. The tail at point $x$ is by definition:

[^6]\[

$$
\begin{equation*}
\operatorname{Tail}_{f_{\mathrm{T}, v}^{0}}(\mathrm{x})=\int_{-\infty}^{\mathrm{x}} \mathrm{z} f_{\mathrm{T}, \mathrm{v}}^{0}(\mathrm{z}) \mathrm{dz}=\mathrm{A} \int_{-\infty}^{\mathrm{x}} \mathrm{z}\left(1+\mathrm{z}^{2} / \mathrm{v}\right)^{-\mathrm{b}} \mathrm{dz} \tag{A7}
\end{equation*}
$$

\]

We change the variable $u=z^{2} / v$, hence $z d z=v d u / 2$. The integral of equation (A7) becomes:

$$
\begin{align*}
\operatorname{Tail}_{f_{T, v}^{0}}(x) & =A \frac{v}{2} \int_{-\infty}^{\frac{x^{2}}{v}}(1+u)^{-b} d u \\
& =\frac{A}{2} \frac{v}{-b+1}\left[(1+u)^{-b+1}\right]_{-\infty}^{\frac{x^{2}}{v}}=\frac{v}{2(1-b)}\left(1+\frac{x^{2}}{v}\right) \times A\left(1+\frac{x^{2}}{v}\right)^{-b}  \tag{A8}\\
& =-\frac{v+x^{2}}{v-1} \times f_{T, v}^{0}(x) . \tag{A9}
\end{align*}
$$

In equation (A8), we replace $b$ with its value $(v+1) / 2$. The final expression of the tail is simplified in (A9). In order to be valid we need to have $v>1$. We now apply (A9) in (A4) to find:

$$
\operatorname{CVaR}_{\mathrm{f}_{\mathrm{T}, \mathrm{\mu}, \mathrm{~s}, \mathrm{v}}}=-\frac{1}{\mathrm{p}}\left\{\mu \mathrm{~F}_{\mathrm{T}, v}^{0}\left(\frac{\mathrm{q}-\mu}{\sigma}\right)-\sigma \frac{v+\left(\frac{\mathrm{q}-\mu}{\sigma}\right)^{2}}{v-1} \mathrm{f}_{\mathrm{T}, v}^{0}\left(\frac{\mathrm{q}-\mu}{\sigma}\right)\right\} .
$$

Important: In Excel, the functions related to Student- $t$ distribution consider the degree of freedom $v$ to be an integer. Therefore, calculations cannot be made in standard form, and an additional module is required. The XRealStats.xlam module is used. It must be downloaded from the website ${ }^{2}$, placed in the C:/TP5 directory and activated to use the functions that allow calculations with $v \in R$. The cumulative and density functions are called by T_DIST. The inverse of the cumulative function is $T_{-} I N V$.

## A6. Exponential Generalized Beta type 2 distribution: EGB2

The EGB2 (Exponential Generalized Beta type 2) density has four parameters and is written, according to Kerman and McDonald (2015), for $y \in R$ :

[^7]$$
\mathrm{f}(\mathrm{y} \mid \mu, \sigma, v, \tau)=\frac{\mathrm{e}^{\mathrm{vz}}}{|\sigma| \times \mathrm{B}(v, \tau)\left(1+\mathrm{e}^{\mathrm{z}}\right)^{v+\tau}}
$$
where $\mathrm{z}=(\mathrm{y}-\mu) / \sigma, \mu, \sigma \in \mathrm{R}, v, \tau>0 . \mathrm{B}(\cdot)$ is the standard beta function.

The parameters $v$ and $\tau$ characterize both tail thickness and the asymmetry of the distribution. The distribution has a negative or positive asymmetry, or is symmetrical when $v<\tau$, $v>\tau$ or $v=\tau$ respectively. As for the tail thickness, the smaller the $v$, the thicker the left tail (all other parameters being equal).

The EGB2 includes many parametric distributions as special cases. Specifically, when $v \approx \tau \rightarrow+\infty$, the distribution converges to the normal. In practice, this convergence can be considered to have been reached when $v \approx \tau>15$. When $v=\tau=1$, EGB2 becomes a logistic distribution. Further, lemma 2 of Caivano and Harvey (2014) shows that EGB2 tends toward a Laplace density when $v \approx \tau \approx 0$. Other interesting special cases of EGB2 and GB2 are presented by Kerman and McDonald (2015).

Cummins, Dionne, McDonald, and Pritchett (1990) applies the GB2 to compute reinsurance premiums and quantiles for the distribution of total insurance losses. EGB2 is increasingly used in finance, as the studies by Caivano and Harvey (2014), McDonald and Michelfelder (2016), and in operational risk management (Dionne and Saissi Hassani, 2017).

## A7. CVaR of a Skew-Normal distribution: SN2

The definition of the density of Skew-Normal (SN2) of Fernandez et al. (1995) for $\mathrm{y} \in \mathrm{R}$ can be written as:

$$
\begin{equation*}
\mathrm{f}_{\mathrm{SN} 2, \mu, \sigma, v}(\mathrm{y})=\frac{2 v}{\sigma \sqrt{2 \pi}\left(1+v^{2}\right)}\left\{\exp \left(-\frac{1}{2}\left(\frac{\mathrm{y}-\mu}{\sigma}\right)^{2} v^{2}\right) \mathrm{I}_{(\mathrm{y}<\mu)}+\exp \left(-\frac{1}{2}\left(\frac{\mathrm{y}-\mu}{\sigma}\right)^{2} \frac{1}{v^{2}}\right) \mathrm{I}_{(\mathrm{y} \geq \mu)}\right\} \tag{A10}
\end{equation*}
$$

where $\mu \in \mathrm{R}, \sigma>0, \nu>0$. SN2 refers to the classification proposed by Rigby et al. (2014).
If $v<1$, asymmetry is to the left (negative returns); if $v>1$, asymmetry is positive. When $v=1$, we return to a normal (symmetrical) distribution. This density is also useful to compute capital in
operational risk management, as in the study by Dionne and Saissi Hassani (2017). A random variable $\mathrm{Y} \sim \mathrm{F}_{\mathrm{SN} 2, \mu, \sigma, v} \Rightarrow \mathrm{Z}=(\mathrm{Y}-\mu) / \sigma \sim \mathrm{F}_{\mathrm{SN} 2, v}^{0}$. For $\mathrm{z}<0$, only the left side of the equation (A10) is non-zero. The reduced density is then written as:

$$
\mathrm{f}_{\mathrm{SN} 2, \mathrm{v}}^{0}(\mathrm{z})=\frac{2 \mathrm{v}}{1+\mathrm{v}^{2}} \phi_{0}(\mathrm{z} \times v)
$$

The cumulative at point $\mathrm{z}<0$ is written as:

$$
\mathrm{F}_{\mathrm{SN} 2, v}^{0}(\mathrm{z})=\int_{-\infty}^{\mathrm{z}} \mathrm{f}_{\mathrm{SN} 2, v}^{0}(\mathrm{t}) \mathrm{dt}=\frac{2}{1+v^{2}} \Phi_{0}(\mathrm{z} \times \mathrm{v}) .
$$

The functions $\phi_{0}(\cdot)$ and $\Phi_{0}(\cdot)$ designate the cumulative and the reduced centered normal density $\mathrm{N}(0,1)$. The previous equation allows us to find the expression of the VaR at the confidence level $(1-\mathrm{p})$ :

$$
\begin{align*}
\mathrm{P}(\mathrm{Y} \leq \mathrm{q})= & \mathrm{P}\left(\mathrm{Z} \leq \frac{\mathrm{q}-\mu}{\sigma}\right) \Rightarrow \mathrm{F}_{\mathrm{SN} 2, v}^{0}\left(\frac{\mathrm{q}-\mu}{\sigma}\right)=\mathrm{p} \\
& \frac{2}{1+v^{2}} \Phi_{0}\left(\frac{\mathrm{q}-\mu}{\sigma} \times v\right)=\mathrm{p} \\
\mathrm{q}= & \mu+\sigma \frac{1}{v} \Phi_{0}^{-1}\left(\mathrm{p} \frac{1+v^{2}}{2}\right) \tag{A11}
\end{align*}
$$

The expression (A11) is valid only if $\mathrm{p}\left(1+v^{2}\right) / 2 \leq 1$, otherwise $\Phi^{-1}(\cdot)$ would not be defined. This requires that $v \leq \sqrt{2 / p-1}$.

The expression of the tail is developed as follows:

$$
\begin{align*}
& \operatorname{Tail}_{\text {SN } 2, v}(\mathrm{x})=\int_{-\infty}^{\mathrm{x}} \mathrm{zf} f^{0}(\mathrm{z}) \mathrm{dz}=\int_{-\infty}^{\mathrm{x}} \frac{2 v}{1+v^{2}} \mathrm{z} \phi_{0}(\mathrm{z} \times v) \mathrm{dz} \\
& =\frac{2 v}{1+v^{2}} \int_{-\infty}^{\times \times v} \frac{u}{v} \phi_{0}(\mathrm{u}) \frac{d u}{v}=\frac{2}{v\left(1+v^{2}\right)}\left[-\phi_{0}(\mathrm{u})\right]_{-\infty}^{\mathrm{x} v} \\
& =-\frac{2}{v\left(1+v^{2}\right)} \phi_{0}(\mathrm{x} \times v) . \tag{A12}
\end{align*}
$$

Equation (A12) is obtained by changing the variable $u=z \times v$ and using equation (A5a). Equations (A11) and (A12) in (A4) give the expression of CVaR:

$$
\mathrm{CVaR}_{\mathrm{SN} 2, \mu, \sigma, v}=-\frac{1}{\mathrm{p}}\left\{\frac{2}{1+v^{2}}\left[\mu \Phi_{0}\left(\frac{\mathrm{q}-\mu}{\sigma} v\right)-\sigma \frac{1}{v} \phi_{0}\left(\frac{\mathrm{q}-\mu}{\sigma} v\right)\right]\right\} .
$$

Again, when $v=1$ we find the CVaR of $\mathrm{N}(\mu, \sigma)$.

## A8. Skewed Exponential Power type 3 Distribution: SEP3

Fernandez et al. (1995) defined this distribution. SEP3 refers to the classification proposed by Rigby et al. (2014). The density of SEP3 is written as:

$$
\mathrm{f}_{\mathrm{SEP} 3, \mu, \sigma, v, \tau}(\mathrm{y})=\frac{\mathrm{c}}{\sigma}\left\{\exp \left(-\frac{1}{2}\left|\frac{\mathrm{y}-\mu}{\sigma} v\right|^{\tau}\right) \mathrm{I}_{(\mathrm{y}<\mu)}+\exp \left(-\frac{1}{2}\left|\frac{\mathrm{y}-\mu}{\sigma} \frac{1}{v}\right|^{\tau}\right) \mathrm{I}_{(\mathrm{y} \geq \mu)}\right\}
$$

where $c=v \times \tau \times\left[\left(1+v^{2}\right) 2^{1 / \tau} \Gamma(1 / \tau)\right]^{-1}$ and where $\mu \in R, \sigma>0, v \in R, \tau>0$. They are respectively the parameters of location, scale, asymmetry, and tail thickness. SEP3 has as special cases the SN2 when $\tau=2$ and a Laplace distribution (asymmetric version) when $\tau=1$. Note that other names exist in the literature to designate distributions comparable to SEP3, such as AP (Asymmetric Power) and AEP (Asymmetric Exponential Power).

SEP3 can be leptokurtic when $\tau<2$ or platykurtic when $\tau>2$ (see Figure A1). VaR and CVaR calculations use gamma functions and the gamma distribution, as shown in the next section.

Figure A1: Plots of SEP3 with different values of $\tau$ and $v$

## A9. VaR and CVaR of SEP3

As we did for SN2, we develop the expression of reduced cumulative of SEP3 for $\mathrm{z}<0$ (left tail) by writing:

$$
\begin{align*}
\mathrm{F}_{\mathrm{SEP} 3, v, \tau}^{0}(\mathrm{z}) & =\int_{-\infty}^{z} \frac{\tau v}{\left(1+v^{2}\right) 2^{1 / \tau} \Gamma(1 / \tau)} \times \exp \left(-\frac{1}{2}|\mathrm{w} v|^{\tau}\right) \mathrm{dw} \\
& =\frac{2^{1 / \tau}}{v \tau} \frac{\tau v}{\left(1+v^{2}\right) 2^{1 / \tau} \Gamma(1 / \tau)} \int_{(z v)^{\tau} / 2}^{+\infty} \mathrm{u}^{1 / \tau-1} \mathrm{e}^{-u} \mathrm{du}  \tag{A13}\\
& =\frac{1}{\left(1+v^{2}\right) \Gamma(1 / \tau)} \int_{(z v)^{\tau} / 2}^{+\infty} \mathrm{u}^{1 / \tau-1} \mathrm{e}^{-u} \mathrm{du} \tag{A14}
\end{align*}
$$

Equation (A13) is immediate after the change of variable $u=(-w v)^{\tau} / 2$ and by positing $s=-z>0$. Note that the inside of the integral $u^{1 / \tau-1} e^{-u} d u$ is reminiscent of the gamma function. We need the complete gamma function $\Gamma(\cdot)$ and its incomplete version $\gamma(\cdot, \cdot)$, which are defined by:

$$
\begin{gathered}
\gamma(\mathrm{a}, \mathrm{r})=\int_{0}^{\mathrm{r}} \mathrm{t}^{\mathrm{a}-1} \mathrm{e}^{-\mathrm{t}} \mathrm{dt} \quad \mathrm{a}>0, \mathrm{r}>0 \\
\Gamma(\mathrm{a})=\int_{0}^{+\infty} \mathrm{t}^{\mathrm{a}-1} \mathrm{e}^{-\mathrm{t}} \mathrm{dt}
\end{gathered} \quad \mathrm{a}>0 .
$$

Parameter $a$ is for the shape of these functions. It is easy to see that $\Gamma(\mathrm{a})=\gamma(\mathrm{a},+\infty)$. We also have a distribution that bears the same name, i.e. gamma, ${ }^{3}$ whose cumulative parameter shape $=\mathrm{a}$ (and scale $=1$ because it is standardized) evaluated at the point $\mathrm{x}>0$. It is written as $\mathrm{G}_{\mathrm{a}}(\mathrm{x})=[\Gamma(\mathrm{a})]^{-1} \gamma(\mathrm{a}, \mathrm{x})$. The calculation of $\mathrm{F}_{\mathrm{SEP} 3, v, \tau}^{0}(\mathrm{z})$ can be obtained from equality (A14):

$$
\begin{align*}
\mathrm{F}_{\mathrm{SEP} 3, v, \tau}^{0}(\mathrm{z}) & =\frac{1}{\left(1+v^{2}\right) \Gamma(1 / \tau)} \int_{(\mathrm{zv})^{\tau} / 2}^{+\infty} \mathrm{u}^{1 / \tau-1} \mathrm{e}^{-\mathrm{u}} \mathrm{du} \\
& =\frac{1}{\left(1+v^{2}\right) \Gamma(1 / \tau)}\left\{\int_{0}^{+\infty}-\int_{0}^{(z)^{\tau} / 2}\right\}=\frac{1}{\left(1+v^{2}\right)} \frac{\Gamma(1 / \tau)-\gamma\left(1 / \tau,(\mathrm{zv})^{\tau} / 2\right)}{\Gamma(1 / \tau)}  \tag{A15}\\
& =\frac{1}{1+v^{2}}\left(1-\mathrm{G}_{1 / \tau}\left(\frac{|\mathrm{zv}|^{\tau}}{2}\right)\right) \tag{A16}
\end{align*}
$$

Equality (A15) is a cut-off of the integral's bounds that allows finding the gamma functions. To save space, we have not inserted the complete mathematical expressions of the two integrals in (A15), which are the same as in the previous equation. The expression is simplified by using the cumulative $G_{1 / \tau}($ shape $=1 / \tau$ and scale $=1)$. By inverting $(A 16)$, the quantile of VaR at the degree of confidence $(1-p)$ is immediate:

[^8]\[

$$
\begin{aligned}
\mathrm{F}_{\mathrm{SEP} 3, v, \tau}^{0}\left(\frac{\mathrm{q}-\mu}{\sigma}\right) & =\mathrm{p} \\
\mathrm{q} & =\mu+\sigma \times \frac{\left[2 \times \mathrm{G}_{1 / \tau}^{-1}\left(1-\mathrm{p}\left(1+v^{2}\right)\right)\right]^{1 / \tau}}{v}
\end{aligned}
$$
\]

The calculation of the tail of SEP3 is similar to that done for the cumulative, but with a shape $2 / \tau$ parameter for $\mathrm{x}<0$ :

$$
\begin{align*}
\operatorname{Tail}_{\text {SEP } 3, v, \tau}(x) & =\int_{-\infty}^{x} z f^{0}(z) d z=\int_{-\infty}^{x} c \times z \times \exp \left(-\frac{1}{2}|z v|^{\tau}\right) d z \\
& =\frac{-2^{1 / \tau}}{v\left(1+v^{2}\right) \Gamma(1 / \tau)} \int_{(-x v)^{\tau} / 2}^{+\infty} u^{2 / \tau-1} e^{-u} d u \\
& =\frac{-2^{1 / \tau}}{v\left(1+v^{2}\right) \Gamma(1 / \tau)} \Gamma(2 / \tau)\left(1-G_{2 / \tau}\left(\frac{|x v|^{\tau}}{2}\right)\right) . \tag{A17}
\end{align*}
$$

Finally, by putting (A16) and (A17) in (A4) we find:

Remember that $\mathrm{G}_{\mathrm{n} / \tau}(\mathrm{x})$ is the cumulative gamma distribution of shape $=\mathrm{n} / \tau$ and scale $=1$ evaluated at point $x$. When $\tau=2$, we return to SN 2 . If $\tau=2$, and $v=1$, we get a normal distribution. The gamma distribution and the complete gamma function exist in standard Excel.

## A10. Skew- $\boldsymbol{t}$ distribution: ST3

The density function of Skew- $t$ of Fernandez et al. (1995), can be written for $x \in R$ as:

$$
\begin{equation*}
\mathrm{f}_{\mathrm{ST3}}(\mathrm{x} \mid \mu, \sigma, v, \tau)=\frac{\mathrm{c}}{\sigma}\left\{\left[1+\frac{v^{2} \mathrm{u}^{2}}{\tau}\right]^{-(\tau+1) / 2} 1_{\mathrm{y}<\mu}+\left[1+\frac{\mathrm{u}^{2}}{v^{2} \tau}\right]^{-(\tau+1) / 2} 1_{\mathrm{y} \geq \mu}\right\} \tag{A18}
\end{equation*}
$$

where $u=(x-\mu) / \sigma ; \quad \mu \in R ; \quad \sigma, v, \tau>0$, and $c=2 v\left[\left(1+v^{2}\right) B(1 / 2, \tau / 2) \tau^{1 / 2}\right]^{-1}$.
ST3 refers to the classification proposed by Rigby et al. (2014). For $z<0$, its reduced density and cumulative are:

$$
\mathrm{f}_{\mathrm{ST} 3, \tau}^{0}(\mathrm{z})=\frac{2 v}{1+v^{2}} \mathrm{f}_{\mathrm{T}, \tau}^{0}(\mathrm{zv}) \text { and } \mathrm{F}_{\mathrm{ST} 3, \tau}^{0}(\mathrm{z})=\frac{2}{1+\mathrm{v}^{2}} \mathrm{~F}_{\mathrm{T}, \tau}^{0}(\mathrm{zv})
$$

where $\mathrm{f}_{\mathrm{T}, \tau}^{0}($.$) and \mathrm{F}_{\mathrm{T}, \tau}^{0}($.$) are the reduced density and cumulative of a Student- t$. The tail at point x is:

$$
\begin{aligned}
\operatorname{Tail}_{\mathrm{f}_{\mathrm{ST}}^{0}}(\mathrm{x}) & =\int_{-\infty}^{\mathrm{x}} \mathrm{zf}_{\mathrm{ST3}}^{0}(\mathrm{z}) \mathrm{dz}=\frac{2 v}{1+v^{2}} \int_{-\infty}^{\mathrm{x}} \mathrm{z} \mathrm{f}_{\mathrm{T}, \tau}^{0}(\mathrm{zv}) \mathrm{dz} \\
& =\frac{2}{v\left(1+v^{2}\right)} \int_{-\infty}^{\mathrm{xv}} \mathrm{u}_{\mathrm{T}, \tau}^{0}(\mathrm{u}) \mathrm{du} \\
& =\frac{2}{v\left(1+v^{2}\right)} \operatorname{Tail}_{\mathrm{f}_{\mathrm{T}, \tau}^{0}}(\mathrm{x} v)
\end{aligned}
$$

Hence, $\mathrm{F}_{\mathrm{ST} 3, \tau}^{0}\left(\mathrm{q}_{0}\right)=\mathrm{p} \Rightarrow \operatorname{VaR}_{\mathrm{ST} 3}=-\mathrm{q}=-\left\{\mu+\sigma \frac{1}{v} \mathrm{~F}_{\mathrm{T}, \tau}^{0-1}\left(\mathrm{p} \frac{1+v^{2}}{2}\right)\right\}$
Note the similarity with SN2 expressions. We now apply (A4) and (A9) to find

$$
\begin{align*}
\operatorname{CVaR}_{\mathrm{f}} & =-\frac{1}{\mathrm{p}}\left\{\mu \mathrm{~F}_{\mathrm{ST} 3}^{0}\left(\frac{\mathrm{q}-\mu}{\sigma}\right)+\sigma \operatorname{Tail}_{\mathrm{f}^{0}}\left(\frac{\mathrm{q}-\mu}{\sigma}\right)\right\} \\
& =-\frac{2}{\mathrm{p}\left(1+v^{2}\right)}\left\{\mu \mathrm{F}_{\mathrm{T}, \tau}^{0}\left(\frac{\mathrm{q}-\mu}{\sigma} v\right)-\sigma \frac{1}{v} \frac{\tau+\left(\frac{\mathrm{q}-\mu}{\sigma} v\right)^{2}}{\tau-1} \mathrm{f}_{\mathrm{T}, \tau}^{0}\left(\frac{\mathrm{q}-\mu}{\sigma} v\right)\right\} \tag{A20}
\end{align*}
$$

## A11. Optimal portfolio calculation

We first introduce the relative VaR and CVaR. Relative VaR, denoted VaRr, is the distance between a given quantile of return distribution and its mean. Relative CVaR, or CVaRr, can be introduced as CVaR coverage including the expected return. Their expressions are: $\operatorname{VaRr}^{\mathrm{p}}=\operatorname{VaR}^{\mathrm{p}}+\mathrm{E}\left[\mathrm{Y}_{\mathrm{t}}\right]$ and $\mathrm{CVaRr}^{\mathrm{p}}=\mathrm{CVaR}^{\mathrm{p}}+\mathrm{E}\left[\mathrm{Y}_{\mathrm{t}}\right]$

We begin by demonstrating that optimal portfolio weights are identical minimizing VaRr or CVaRr at $\mathrm{p}=5 \%$. Assuming normal returns for now, the portfolio measures are:

$$
\begin{gather*}
\operatorname{VaR}=-\mu_{\text {portfolio }}-\sigma_{\text {portfolio }} \times \Phi_{0}^{-1}(\mathrm{p}) \quad \text { and } \operatorname{VaRr}=-\sigma_{\text {portfolio }} \times \Phi_{0}^{-1}(\mathrm{p})  \tag{A21}\\
\mathrm{CVaR}=-\mu_{\text {portfolio }}+\sigma_{\text {portfolio }} \frac{\phi_{0}\left(\Phi_{0}^{-1}(\mathrm{p})\right)}{\mathrm{p}} \text { and } \mathrm{CVaRr}=\sigma_{\text {portfolio }} \frac{\phi_{0}\left(\Phi_{0}^{-1}(\mathrm{p})\right)}{\mathrm{p}} \tag{A22}
\end{gather*}
$$

where $\sigma_{\text {portfolio }}=\sqrt{\beta^{\mathrm{T}} \Sigma \beta}, \beta$ is security weights vector, $\Sigma$ is the return variance-covariance matrix, $\Phi_{0}^{-1}(\cdot)$ and $\phi_{0}^{-1}(\cdot)$ are the quantile and densty functions of $\mathrm{N}(0,1)$. Since $\Phi_{0}^{-1}(\mathrm{p})$ and $\phi_{0}\left(\Phi_{0}^{-1}(\mathrm{p})\right) / \mathrm{p}$ are constant, both $\operatorname{VaRr}$ and CVaRr are minimized on $\sqrt{\beta^{\mathrm{T}} \Sigma \beta}$ alone. Hence, the optimal portfolio is the same. Moreover, optimal weights are independent of p .

Table A. 2 shows the results ${ }^{4}$. The portfolio mean and standard deviation are reported next to those of the three assets. We focus on VaR line in order to comment weighted sum column. The portfolio $\operatorname{VaR}=2.079 \% . \mathrm{R}=(2.621 \%, 4.321 \%, 2.288 \%)$ represents the VaR vector of individual assets (normal returns, equation (A21)). Weighted sum column shows the vector product $\beta^{\mathrm{T}} \mathrm{R}=2.725 \%$, which calculate the risk of holding the same proportions of the assets separately (no correlation effect). The Difference column shows $2.079-2.725 \approx-0.64 \%$. The portfolio is thus 64 basis points less risky than holding separate assets. This is consistent with the diversification principle. VaRr, CVaR, and CVaRr follow the same pattern.

[^9]Table A. 2
Optimal portfolio (normal model)

*Variance is multiplied by 100 to show m decimal digits.

[^1]:    ${ }^{1} \mathrm{CVaR}$ is also called expected shortfall in the literature. Both measures are equivalent, with continuous distributions without jumps (Rockafellar and Uryasev, 2002). See also Dionne (2019).
    ${ }^{2}$ In this paper, we use the letter $p$ to refer to the probability that the VaR is exceeded, and 1-p for the corresponding confidence level. The $p$-value notation is for statistical tests.

[^2]:    ${ }^{3}$ https://www.nber.org/cycles.html

[^3]:    *Variances and covariances are multiplied by 100 to show more decimal places.

[^4]:    ${ }^{4}$ This is a sufficient condition on $G_{1}$. If not satisfied, Theorem 5.2 in Fissler and Ziegel (2016) shows that the function defined by $f\left(v_{t}\right)=-v_{t} G_{2}(-e)+G_{1}\left(-v_{t}\right)$ must be strictly increasing with respect to $v_{t}$.

[^5]:    *** $\mathrm{p}<0.01 \quad * * \mathrm{p}<0.05 ; p$-values in parentheses below the statistics

[^6]:    ${ }^{1}$ There is another way to write the constant A with the gamma function $\Gamma(\cdot)$ instead of the beta function.

[^7]:    ${ }^{2}$ http://www.real-statistics.com/free-download/

[^8]:    ${ }^{3}$ Under the same "gamma" designation, three entities can be distinguished: the function $\Gamma($.$) (complete from 0$ to $+\infty$ ) and the incomplete function (its integral stops at a point $r<+\infty$ ). The third entity is the gamma distribution with two parameters: shape and scale.

[^9]:    ${ }^{4}$ See also the Excel file available on the Canada Research Chair website at https://chairegestiondesrisques.hec.ca/en/ seminars-and-publications/book-wiley/
